Abstract. We look at the drying process in a simple glass channel with dominant capillary effects as is the case in microfluidics. We find drying kinetics commonly observed for confined geometry, namely a constant period followed by a falling rate period. From visualization of the air/water interface with high resolution, we observe that the drying rate decreases without a drying front progression although this is the usually accepted mechanism for confined geometries. We show with FEM that in our specific geometry the falling rate period is due to changes in the shape of the air-water interface at the free surface where most evaporation occurs. Our simulations show that the sensitivity of the drying rate to the shape of the first air-water interface from the sample free surface implies that slight changes of the wetting or pinning conditions can significantly modify the drying rate.

### **1** Introduction

Drying of channels is of great interest for microfluidics 2 process where drying induces passive flow [1], cools down 3 devices [2], concentrates suspension [3,4] and leads to con-4 trolled crystal growth [5]. Besides capillary channels are 5 also considered as model porous media in which it is possi-6 ble to observe the details of the air-water interface in time. 7 Studying drying kinetics from such simple configurations 8 makes it possible to understand the basics mechanisms 9 involved in evaporation from a confined geometry. 10

So far studies on 2D porous systems mainly focused 11 on air/liquid interfaces throughout the sample (Invasion-12 Percolation process) [6–8]. Detailed observations were pos-13 sible in unique long and slender channels that are closed at 14 one end and exposed to the atmosphere at the other end. 15 It was shown that evaporation from a cylindrical channel 16 decreases with  $1/\sqrt{t}$  as water vapor diffuses over an in-17 creasing length from the meniscus to the channel end [9]. 18 But changing the channel cross sectional shape strongly 19 influences the water distribution. In particular the drying 20 rate from channels with corners remains constant and en-21 hanced relatively to vapor diffusion because liquid films 22 in the corners extend to the free surface and sources the 23 water for evaporation [10-12]. 24

In [10, 11, 13] the subsequent decrease of the drying rate was associated with a depinning of the liquid films from the free surface resulting from gravitational and viscous effects. The high wettability of the solid by the fluid is necessary for water to stay in channel edges as water wets more surfaces. If the contact angle is too high, films are geometrically impossible in a right angle corner [10, 14]; in this situation drying is a slow diffusive process as in cylindrical tube. Therefore water distribution is very sensitive to wetting or pinning conditions and can modify the drying kinetics.

Drying from 3D porous media exhibits some similarity with drying from simple channels [13, 15, 11, 16], but it is much more difficult to relate the exact shape of the air-liquid interface to the drying rate. Sophisticated 3D imaging tools such as MRI indicate that when a dry front develops the drying rate decreases; but the resolution is 41 not sufficient to determine the distribution of water within individual pores [17–19]. Other studies investigated the 43 wetting of porous media [20–22] without providing much insight into the impact of the exact shape of the liquid-air interface on the drying rate.

It is useful to recall the drying principles of hydrophilic confined geometries [13,23-26]. Regardless of the complexity of the material structure (from square capillary to soils) two main stages of drying are observed for an initially water-saturated device. The basic physical origin of these regimes is as follows:

i) Drying rate starts with a Constant Rate Period (CRP), 53 where the drying rate remains constant until the 54

Page 2 of 10

majority of water is evaporated. Here the drying rate is
set by external conditions such as air flow, temperature
and humidity. It has been shown that for this regime
the capillary pressure is sufficient to drive water to the
sample outer surface [23,24].

ii) This is followed by the Falling Rate Period (FRP) 60 where the drying rate decreases and approaches zero. 61 The proposed mechanism for this decrease is that be-62 low a certain saturation value (ratio of water to total 63 volume), viscous dissipation is too high for capillary 64 pressure to source a flow to the outer surface equaling 65 the CRP drying rate. Consequently a drying front in-66 vades the medium causing evaporation to increasingly 67 slow down because water vapor has to diffuse from the 68 receding front to the free surface. 69

Here we study the drying of a single channel having a 70 rectangular cross-section that is held horizontal to remove 71 gravitational effects. We combine high-resolution weighing 72 with microscopy to accurately record the drying process. 73 Similar to porous media, we observe that evaporation rate 74 has two regimes: CRP followed by a FRP. These observa-75 tions lead us to carry out FEM simulations which provide 76 an insight in the origin of these trends. We thus show how 77 capillarity sets the water distribution and the decrease in 78 evaporation rate in our specific geometry is due to vari-79 ations in the shape of the liquid-air interface around the 80 entrance of the channel. 81

### **2** Materials and methods

#### 83 2.1 Glass capillary

We used a borosilicate glass channel with a high-aspect 84 ratio rectangular cross-section (W = 2 mm; H = 0.1 mm, 85  $L = 10 \,\mathrm{mm}$  from Vitrocom<sup>®</sup>). It is important to note that 86 the channel cross section is not perfectly rectangular (see 87 fig. 1b). The glass is cleaned with Isopropanol, and the 88 contact angle is small, between  $5^{\circ}$  and  $10^{\circ}$ . Accordingly 89 when the channel is in contact with deionized water it is 90 filled due to capillary suction. Once filled with water, one 91 of the channel ends is closed off with epoxy glue such that 92 evaporation only occurs at the other end. 93

#### 94 2.2 Drying conditions and measurements

We tracked the drying process of the filled horizontal 95 glass channel using two separate measurements, which are 96 imaging and weighing. For both experiments the temper-97 ature was held at  $25 \,^{\circ}$ C and the relative humidity at 50%98 by flowing air at a rate of  $10 \,\mathrm{mL/min}$  across the channel qq opening. The rate of evaporation was recorded by taking 100 the mass every 25 seconds using a TGA (thermogravimet-101 ric analysis from Texas Instruments). We obtain the mean 102 saturation  $\phi = V_{\text{water}}/V_{\text{water ini}}$  from the ratio of the water 103 current mass to its initial mass. The noise is of the order 104 of  $0.2\,\mu{\rm g}$  and the initial water mass  $m_{\rm water~ini}~\approx~1\,{\rm mg},$ 105 therefore the saturation is obtained with an accuracy of 106

Eur. Phys. J. E (2016) runline to be inserted

Fig. 1. Schematic of the experimental geometry: a glass channel with rectangular-like cross section closed at one end and at the entrance open for evporation. The receeding air/water interface is qualitatively sketched. (b) Channel height, h, measured from the SEM images of our geometry a function of the transverse position, y. The linear approximation is used for modeling (dash line).

 $\phi \approx 2 \cdot 10^{-4}$ . Here we exemplify the repeatability and 107 the uncertainty through a comparison between the re-108 sults on two samples. In a separate experiment we im-109 aged the channel every 10 seconds with a microscope in 110 transmission mode. We measure  $\phi$  from the position of 111 the air/water interfaces as observed from above which ne-112 glects the out-of-plane curvature. Due to this approxima-113 tion, lensing effects of the interface and limited pixel res-114 olution  $(4.3 \,\mu\text{m})$ , the optical values of the saturation are 115 significantly less accurate than those obtained from weigh-116 ing. 117

#### 2.3 Finite element modeling

To understand the drying kinetics, we model the local  $^{119}$  evaporation from the air/water interface by calculating  $^{120}$  the vapor density field, n, implementing 2D FEM using  $^{121}$  MATLAB. We use the function "adaptmesh" to generate the mesh and refine triangles with high vapor gradients.  $^{122}$ 

Fig. 2. Schematic of the domain used for 2D FEM modeling. The air-water interface is shown as a solid black curve, and the dashed lines indicate no-flux boundary conditions. The humidity is fixed at 50% for the gray curve, which is a distance delta away from the channel. F is the local evaporation from the interface and the drying rate J is the flux of water vapor through the channel entrance.

The 2D geometry is justified by the large aspect ratio of 124 in-plane geometric features compared to the much smaller 125 vertical out-of-plane features. We neglect the slight taper-126 ing of the channel rectangular cross-section. For the sim-127 ulations the shape of the interface is externally set; we 128 either use microscopic images or simplified idealizations. 129 3D simulations may have given a more realistic representa-130 tion of the air/water interface shape and of vapor diffusion 131 outside the channel. It seems relevant to keep the 2D for 132 a first distinction of the main phenomena. 133

We assume a quasi-static air-water interface, indeed 134 the vapor diffusion velocity is of the order of  $D/L \approx$ 135  $10^{-3} \text{ m s}^{-1}$ , where water vapor diffusion coefficient is  $D = 2.7 \cdot 10^{-5} \text{ m}^2 \text{ s}^{-1}$ , and far exceeds the experimentally ob-136 137 served drying velocity  $V_{\rm drying} \approx 2 \cdot 10^{-6} \,\mathrm{m \, s^{-1}}$  (see eq. (2)). 138 As a consequence the Laplace equation  $(\Delta n = 0)$  captures 139 the spatial field of vapor density. Along the liquid-air inter-140 face the vapor density is maximal,  $n = n_0 = 23.4 \,\mathrm{g \, m^{-3}}$ . 141 which is indicated by the solid black curve in fig. 2. The 142 external air flow produces a vapor density of  $n = n_0/2$  at 143 a distance  $\delta$  from the channel entrance, shown as a gray 144 curve in fig. 2.  $\delta$  represents the influence of the external 145 conditions during the CRP and does not vary during the 146 experiment. Along the centerline axis and glass wall of the 147 capillary we use a no-flux boundary condition,  $\nabla n \cdot s = 0$ 148 where s is the normal vector, which is shown as dashed 149 lines in fig. 2. We solve for the local evaporation flux 150 along the air/water interface:  $F = -D \cdot \nabla n$ . The dry-151 ing rate is the integral along the channel entrance, J =152  $-\int_{x=0} D \cdot \nabla n \cdot \mathrm{d}s.$ 153

### 154 3 Results

#### 155 3.1 Imaging

Initially the channel is completely filled with water (saturation  $\phi = 1$ ) and over time the air/water interface curves inwards due to water loss from evaporation, while water

remains pinned at both edges of the entrance (see fig. 3a). 159 As drying proceeds a finger invades the channel (see the 160 schematic in fig. 1 and fig. 3b-d). The main meniscus keeps 161 a constant shape (approximately a half-circle of radius 162  $r_{\rm c} = 0.6 \,\mathrm{mm}$ ) and progresses with a constant speed to-163 wards the end of the channel, leaving behind two water 164 layers of constant thickness  $w = 0.4 \,\mathrm{mm}$  along the chan-165 nel edges (see fig. 3c-d). Behind the fingertip air occupies 166 60% of the cross-section. Accordingly, once the saturation 167 has dropped to 0.4 the fingertip has reached the chan-168 nel end the two water layers begin to thin uniformly (see 169 fig. 3e-f). As w becomes of the order of the channel height, 170  $H = 100 \,\mu\text{m}$ , the films are difficult to discern, as shown in 171 fig. 3g. 172

For each position along channel axis, we measure the 173 distance between the interface and the channel edge as 174 the shortest distance separating the two black lines on 175 the upper half of images of fig. 3. In the drying process we 176 observe three characteristic profile shapes which evolve in 177 a self-similar fashion. Starting from the back of the chan-178 nel, these are: the main meniscus, the thin films at the 179 sides and the entrance profile. The main meniscus has a 180 characteristic curved profile, resembling a finger, which 181 advances into the channel (see fig. 3b-d). As the finger ad-182 vances, the side films increase in length while maintaining 183 their width  $w \approx 0.38 \,\mathrm{mm}$  and film thickness is constant for 184  $x > 0.4 \,\mathrm{mm}$  as shown for the times 17–103 min in fig. 4a. 185 As the water films shrink, the entrance profile curves fur-186 ther into the channel and constant thickness is established 187 sooner (at  $x \approx 0.1 \,\mathrm{mm}$  for 163 min, see fig. 4b). Moreover 188 at 163 min the interface has receded by tenths of microns 189 from the entrance of the tube. 190

### 3.2 Drying rates

The mass measurements are sufficiently accurate to allow 192 differentiation for obtaining the evaporation rate, which 193 is shown as a function of saturation in fig. 5. However the 194 derivation procedure tends to increase the impact of data 195 fluctuations. This explains that the final uncertainty on 196 drying rate is of the order of 10% (see an example of two 197 results for the same experiment in fig. 5). Using image 198 analysis to determine the water volume we also obtain 199 the evaporation for shorter times, which is shown as gray 200 curve in fig. 5. The agreement between these two types 201 of measurement is good over the range  $\phi = 0.5$  to 0.9. 202 Accurate measurements at  $\phi = 1$  are difficult, but initially 203 it is clear that the drying rate decreases by more than 204 30% between  $\phi = 1$  and 0.9. The majority of the water 205 evaporates at a constant drying rate, defining the CRP for 206  $\phi = 0.3$  to 0.9. For lower water saturations,  $\phi < 0.3$  the 207 evaporation rate decreases to zero. The drying rate starts 208 to decrease around  $\phi = 0.3-0.25$  then there is a sharp 209 decrease in the range  $\phi = 0.2-0.1$ . 210

### 3.3 FEM using experimentally observed interfaces

We implement the 2D FEM scheme for the interfaces extracted from the channel images (see fig. 3) and obtain the

191

Fig. 3. Top views of the channel (open on the left) at different times during drying: (a) initial and after 17 (b), 34 (c), 68 (d), 103 (e), 137 (f) and 163 min (g). The scale bar denotes 1 mm and applies to all panels.

Fig. 4. (a) Shape of the air/water interface for images from fig. 3, drying times are indicated in minutes. We present here the upper half of the images of the interface. The channel is open at x = 0 and its axis is y = 1 mm. (b) Interface close to the entrance of the channel at the end of the drying. The inset is a zoom on the first 50  $\mu$ m of the channel entrance for the same interfaces.

field of relative humidity in channel air space (see fig. 6). 214 At the beginning, the interface is almost straight at the 215 free surface (fig. 6a) and the vapor gradient is uniform. 216 As the air finger enters (fig. 6b), the air close to the main 217 meniscus is saturated with water vapor. When the main 218 219 meniscus progresses, the air is saturated with water vapor for x > 1.5-2 mm, the liquid water is at equilibrium 220 with the air (fig. 6c). Close to the entrance, the gradient 221 of vapor density is high and so is the local evaporation. 222

The drying rate computed from the 2D FEM, J, remains constant as the main meniscus recedes into the channel and decreases as the films shrink. The modeled drying rate is in good agreement with the weighing and optical measurements, as shown by the gray squares in fig. 5, and we thus have established their utility for gaining further insight into the drying kinetics. 229

# 4 Analysis of the different drying regimes

We perform a comprehensive analysis of the drying process based upon image analysis and TGA measurements coupled with 2D FEM simulations to study the physical origin of the successive evaporation regimes. 234

Fig. 5. Drying rate, normalized at CRP, as a function of the saturation, from two measurements by TGA (black continuous and dotted curves) and from image analysis (gray curve). Times refer to pictures of fig. 3. The gray squares are the drying rate computed from FEM.

#### 4.1 Initial decrease 235

Initially the channel is completely filled and the air-water 236 interface is flat. Consequently the entire interface is the 237 closest to the dry air surrounding the channel, thereby 238 resulting in the greatest drying rate. Assuming there is 239 no air flow in the boundary layer of thickness  $\delta$ , the rate 240 of evaporation is proportional to the gradient of vapor 241 density according to Fick's law: 242

$$\frac{\mathrm{d}m}{\mathrm{d}t_{t=0}} \sim \frac{Dn_0 W H}{2\delta} \,. \tag{1}$$

However we do not have reliable data concerning the dry-243 ing rate in the very first times of a test. In order to deter-244 mine the value of  $\delta$  we compare the drying rate drying rate 245  $J_{\rm CRP}$  predicted from simulations during the CRP (*i.e.* at 246 68 min, see below), using the observed shape of the in-247 terface at that time, to the drying rate measured in that 248 regime. We find  $\delta = 5 \cdot 10^{-5}$  m, and we deduce from (1) 249 that the drying rate at the very beginning of the test, 250 *i.e.* when the interface is straight, should be equal to 3.5251 times the CRP drying rate. The validity of this approach 252 is supported by the good agreement between the drying 253 rate computed by FEM with the first reliable measure-254 ment (see fig. 5). 255

Between the beginning of the test and the CRP the 256 drying rate decreases as the air finger forms and water 257 vapor diffuses over an increasing length (see gray line in 258 fig. 5). Over time the interface becomes increasingly con-259 cave, as shown in fig. 3. Since the evaporation flux de-260 creases with distance from the dry air the drying rate 261

rapidly drops off as the interface starts to become con-262 cave: it is already close to the CRP drying rate after a 263 small decrease of saturation. 26/

#### 4.2 Constant rate period

The Constant rate period (CRP) starts at about 15 min-266 utes and extends from a saturation of 0.9 down to around 267 0.25, making it the dominant feature of the drying rate 268 curve shown in fig. 5. The air finger is established roughly 269 when its length is comparable to its width. Thus we esti-270 mate that the transition to CRP occurs at a saturation around  $\phi = 1 - \frac{(W-2w)^2}{WL}$ . In our geometry, we obtain  $\phi = 0.9$  in very good agreement with observations. More-271 272 273 over if the channel length is increased, this transition will 274 occur at a saturation closer to 1. 275

During this regime a growing finger penetrates deeper 276 into the channel while preserving the interfacial shape at 277 the entrance of the channel (see fig. 3). Capillarity pumps 278 water from the reservoir behind the finger to the entrance 279 where evaporation is primarily occurring [23, 15, 16, 10]. 280 Below we first demonstrate that in CRP viscous dissi-281 pation has a negligible effect on drying, thus capillarity 282 set the water distribution. Then we show that a constant 283 curvature sets the shape of the air/water interface.

The pressure drop due to viscous flow through the side films depends on the mean velocity of the flowing water, which can be approximated using

$$V_{\rm drying} = (1/wH\rho) \,\mathrm{d}m/\mathrm{d}t \approx 2 \cdot 10^{-6} \,\mathrm{m \, s^{-1}},$$
 (2)

where w is the width and H the height (see fig. 8a-b). 288 Accordingly the viscous pressure drop along the side film 289 is of the order of 290

$$\Delta p_{\rm vis} \sim \frac{\mu L}{Hw} V_{\rm drying} \sim 1 \,\mathrm{mPa},$$
 (3)

where  $\mu$  is the viscosity. This pressure drop causes a 291 change in the interfacial curvature of the film. Because the 292 wetting angle is close to zero, and the in-plane curvature is 293 zero, the scale of the pressure as given by Laplace's law is 294  $p_c \sim \frac{\gamma}{H} \sim 1 \,\mathrm{kPa}$  where  $\gamma$  is the surface tension. Therefore 295 the Laplace pressure is order of magnitude larger than the 296 stress associated with viscous flow. Exact computations of 297 the flow [14, 27] suggest that the viscous pressure is 100 298 times higher than in eq. (3) but still much smaller than 299 the capillary pressure. Meter long channels are required 300 for viscous dissipation to be of the same order as capillary 301 pressure. Thus changes in curvature due to viscous flow are 302 negligible compared to the mean curvature. Consequently 303 in this regime the air/water interface has a constant cur-304 vature. Thus the water distribution is at equilibrium and 305 set by the capillarity. 306

The interface observed in CRP has two dominant fea-307 tures, which are the circular concave fingertip and the two 308 side layers. Over time the fingertip moves towards the end 309 of the channel while preserving its shape, and the two side 310 layers maintain their thickness, as shown in fig. 4. The in-311 terface shape is set by the channel cross-sectional shape, 312

265

284 285

286

Fig. 6. Fields of relative humidity  $n/n_0$  for the observed air/water interfaces as shown in fig. 3 (axes scale is millimeter). The air is saturated with water at the air/water interface and  $n/n_0 = 50\%$  at a distance  $\delta$  from the channel entrance (light gray); as shown in fig. 2. The gray scale is common to all figures. The black lines indicate curves of iso-humidity (80, 90 or 99%).

the small wetting angle and a constant mean curvature asshown in fig. 7a-b.

The water distribution is different from the one ob-315 served in a square cross-section channel where four water 316 films are in each of the corners [13, 11]. Since in CRP the 317 curvature is constant we can describe the shape of the 318 interface by taking into account channel geometry [28]. 319 Thus the sum of the in-plane curvature and the out-of-plane curvature  $\frac{1}{r_{xy}} + \frac{1}{r_{yz}}$  is constant because due to the small wetting angle the second radius is half the channel 320 321 322 height,  $r_{yz} \approx \frac{h}{2}$ . 323

As illustrated in fig. 1a and measured with SEM, 324 the spacing is larger  $(H_{\text{max}} = 115 \,\mu\text{m})$  in the center 325 and narrower  $(H_{\min} = 95 \,\mu\text{m})$  at the edges. We con-326 sider that the variation is linear from the edge to the 327 center, as shown in fig. 1b. We can calculate the curva-328 ture in some specific points of the air/water interface. At 329 the main meniscus the total curvature is approximately 330  $2/H_{\rm max} + 1/r_{\rm c} \approx 19 \,{\rm mm}^{-1}$ . The straight portion of in-331 terface is  $w = 0.4 \,\mathrm{mm}$  away from the edge, therefore the 332 vertical spacing is  $h = 105 \,\mu \text{m}$  (see fig. 1b) and the to-333 tal curvature  $2/h \approx 19 \,\mathrm{mm^{-1}}$ . Finally, at the entrance of 334 the channel, using w as radius of curvature (but in a con-335 vex shape) in the plane of observation and the minimum 336 spacing (along the edge) as the second curvature, we find 337  $2/H_{\rm min} - 1/w \approx 18.5 \,\mathrm{mm}^{-1}$ . In agreement with low vis-338 cous dissipation (eqs. (2) and (3)), the total curvature is 330 uniform along the interface and capillary equilibrium is 340 maintained everywhere. 341

More generally capillary equilibrium and geometry set the existence of two thick films rather than four corners films. The radius of curvature r varies linearly with the distance from the edge as  $2r = h = a(w + m) + H_{\min}$ , where a is the slope of the spacing. Decreasing w also decreases the radius of curvature r as shown by the circular arc (gray dotted), simultaneously  $r_c$  increases. The geometrical constraints of fig. 7 link the curvature at the main meniscus and the thickness w. Moreover the curvature at the main meniscus (left term) and along the films (right term) are equal 352

$$\frac{1}{r_{\rm c}(w)} + \frac{2}{H_{\rm max}} = \frac{2}{h(w)} \,. \tag{4}$$

w is then the solution of a quadratic equation and depends on the slope a and the aspect ratio  $\frac{W}{H_{\min}}$  (see fig. 7c). A given geometry is characterized by  $(a, \frac{W}{H_{\min}})$  which accept a unique films thickness w setting a constant curvature at 353 354 355 356 the main meniscus and the films. A negative value for w357 means that water is only present in the 4 corners where 358 air/water interface can adjust its curvature (see fig. 7b). In our geometry,  $\frac{W}{H_{\min}} = 21$  and  $a = 2 \cdot 10^{-2}$ , we obtain w = 0.4 mm in very good agreement with our observations (see fig. 4). The same slope a with  $\frac{W}{H_{\min}} = 10$  would lead 359 360 361 362 to w < 0. As a is close to 0, the spacing is constant and 363 films curvature is constant with thickness thus w < 0. 364 As the section gets closer to a square,  $\frac{W}{H_{\min}}$  approaches 1, there are no values for *a* where w > 0 and the water 365 366 is always in 4 corners films in agreement with previous 367 observations [10]. For high aspect ratio, the films are very 368 likely, indeed the smallest a such as w > 0 scales with 369  $\frac{H_{\min}}{W}$ . 370

To gain further insight into the evaporation process, we perform numerical simulations where the evaporation flux is calculated for a given shape. We implement the 2D FEM scheme for the interfaces extracted from the channel images of air/water interface and obtain the field of

Fig. 7. (a) Schematic of the channel in the plane of observation. The width W constrains the water film width w < W/2, and the in-plane radius of in-plane curvature of the main meniscus  $r_c < \frac{W}{2} - w$ . (b) Side view of the channel showing the interface with two side layers (w > 0) and four corner layers (w < 0). The channel spacing has a slope a, and the in-plane projected width of the meniscus is m. (c) Thickness of the water layer w as a function of the slope a calculated from eq. (4) setting a constant curvature for different aspect ratios of the channel  $\frac{W}{H_{\min}}$ . The solid curve shows our geometry where  $\frac{W}{H_{\min}} = 21$  and the dashed vertical line shows the value of our slope,  $a = 2 \cdot 10^{-2}$ . The values of w < 0 correspond to situation where the layers are in the 4 corners as depicted on (b).

relative humidity in channel air space (see fig. 6). At the 376 beginning, the interface is almost straight at the free sur-377 face (fig. 6a) and the vapor gradient is uniform. As the 378 main meniscus progresses the air is saturated with water 379 vapor for x > 1.5-2 mm, the liquid water is at equilib-380 rium with the air (fig. 6c). During the progression of the 381 main meniscus, the computed drying rate J remains con-382 stant as the measured drying rate (see fig. 5). The field 383 of vapor density n inside the channel shows that the air 384 close to the main meniscus is saturated with water vapor 385  $(n > 0.99 \cdot n_0)$  as soon as the shape of the air/water inter-386 face is established (see fig. 6 b and c). Therefore the water 387 inside the channel is almost at equilibrium with the air 388 and extremely slowly evaporates. Close to the entrance, 389 the gradient of vapor density is high resulting in a high 390 local evaporation flux. This is confirmed by the compu-391 tation of the local evaporation F; its profile is constant 392 in time and decreases exponentially in the channel with a 393 characteristic length  $x_0 \approx 0.4$  mm, as shown in fig. 8. The 394 main contribution to the drying rate thus comes from the 395 interface close to the free surface which sets the drying 396 rate; as the shape of the water layer is constant during 397 the CRP, so is the drying rate. The localization of evap-398 oration flux at the channels entrance is similar to the ob-399 servation in drops where water evaporates mostly at the 400

Fig. 8. Evaporating flux F along the air/water interface in the entrance region for five of the configurations shown in fig. 3.

contact line [29]. Moreover it creates a screening effect in our confined geometry inhibiting evaporation from inside air/water interface. 403 As long as the liquid film along the channel sides is continuous we should have an immediate supply of water towards the free surface, leading *a priori* to a constant drying rate imposed by external conditions down to low saturation. Actually the drying rate is constant down to a saturation of  $\phi = 0.3$ , then it significantly decreases while there is still a continuous film along the channel (see fig. 5).

#### 411 4.3 Falling rate period

Once the finger extends to the end of the channel the 412 evaporating fluid is sourced from the remaining regions; 413 the saturation  $\phi \approx \frac{2w}{W}$  is independent of the channel length 414 L. The side layers shrink and the air/water interface moves 415 away from the entrance, as shown in fig. 4. Consequently 416 the drying rate diminishes for  $\phi = 0.3$ , as shown by our 417 simulations (see fig. 5). Accordingly this regime is called 418 the falling rate period. We discuss two simplified scenarios 419 for the evolving shape of the two side layers to better 420 understand our observed drying process. 421

The decrease of the drying rate occurs as capillary ef-422 fects are still dominant (see eqs. (2) and (3)). Moreover 423 the channel remains wetted up to its entrance until the 424 very end of the observation ( $\varphi \approx 0.06$ ). Since this situa-425 tion is similar to that assumed during the CRP in porous 426 media we expect the drying rate to be constant until the 427 very low residual saturation when permeability in the re-428 maining films is too low to pump water to the surface and 429 a drying front progresses. Here we observe a strong de-430 crease of the drying rate in an unexpected configuration. 431 The drying rate decreases whereas the usual conditions for 432 the CRP are still fulfilled, namely capillary effects able 433 to pump the liquid from the porous medium up to the 434 entrance and continuous films covering the solid surfaces 435 throughout the sample. 436

This paradox is consistent with water diffusion from 437 the air/water interface. In porous media, it has been 438 shown that the drying rate depends on the saturation as 439 long as the diffusion length  $\delta$  is smaller than the distance 440 between wet patches [22]; this situation is similar to our 441 experiments where  $\delta \ll W$ , therefore the shape of the 442 wet patches influences the drying rate. On the contrary, if 443 this condition is not verified, the drying rate remains con-444 stant as the surface saturation decreases and the shape 445 of the water patches does not influence the drying rate. 446 At drying times 137 and  $163 \min$ , the drying rate com-447 puted by FEM J is lower than in the CRP (see fig. 5) 448 in agreement with the experiments. Thus the evaporation 449 close to the entrance drops due to change in the inter-450 face shape observed in the inset of fig. 4b. Moreover the 451 flux decay inside the channel is less pronounced, which 452 means that a longer portion of the interface now signifi-453 cantly contributes to the drying rate (see inset of fig. 8). 454 The geometrical parameters responsible for the decrease 455 are not clear. During the FRP, the water layer thickness 456 w decreases, but also the shape of the air/water interface, 457 which is constant during the CRP, curves and steps away 458 from the entrance (see fig. 4b). 459

The high contribution to evaporation of the interface 460 close to the free surface of the sample also implies that the 461 thickness of the liquid layers beyond the entrance length 462 has no impact on the drying rate. Since our experimental 463 data show a strong decrease of the drying rate in a regime 464 where the film thickness decreases and the air/water inter-465 face shape evolves, we consider two simple configurations 466 based on the water layer thickness w and the angle  $\alpha$ , *i.e.* 467 the slope of the interface from the entrance (see schemat-468 ics in fig. 9). These unrealistic shapes do not represent the 469 evolution of observed interfaces, nevertheless we use them 470 to understand the influence of these two parameters on 471 the drying rate independently. 472

As the film thickness (w) decreases, the local evapora-473 tion F in the channel has a peak at the entrance and de-474 cays exponentially with a length scaling with the air layer 475  $r_{\rm c} = W/2 - w$  (see fig. 9a) which is consistent with 1D 476 diffusion model [11]. The drying rate J decreases linearly 477 with w and the saturation, taken as  $\phi = \frac{2w}{W}$ ; J reaches a 478 minimum value  $J_1 \approx 0.2 \cdot J_0$  as  $w \to 0$  (see fig. 9c). The 479 variation of w is not sufficient to explain the observed de-480 crease of the drying rate in the FRP. Keeping w constant, 481 the variation of the slope  $\alpha$  has a dramatic impact on the 482 drying rate. J is divided by 2 as  $\alpha$  decreases from 90° to 483  $70^{\circ}$  corresponding to a small decrease of the mean water 484 saturation (see fig. 9c). Thus the change of angle  $\alpha$  and 485 variation of the interface at the entrance may explain the 486 decrease of drying rate in a short range of saturation. As 487  $\alpha \to 0^{\circ}$ , J reaches the same value  $J_1$  as for decreasing w. 488 More generally,  $J - J_1$  is proportional to w. For different w, 489 evolution of  $(J - J_1)/w$  with  $\alpha$  collapses with  $\cot(\alpha) \cdot w$ , 490 the distance of junction between the slope and the con-491 stant thickness region (see fig. 9b). The decrease of the 492 drying rate extends to a distance  $\cot(\alpha) \cdot w \approx W$ . Thus 493 as the entrance region extends over a distance larger than 494 the width of the tube, the drying rate is constant at  $J_1$ 495 independently of w and  $\alpha$ . 496

As w < H eq. (3) underestimates the viscous dissi-497 pation which now depends on the corners sharpness [13, 498 11,27,14]. The progression of a drying front seems to de-499 scribe well the drying kinetics until the very low saturation 500  $\phi \approx 10^{-4}$  which is the accuracy limit of our mass mea-501 surements. This decrease of the drying rate occurs only at 502 extremely low saturation and after a first relatively long 503 period of falling rate, therefore it is not significant in the 504 drying kinetics of our geometry. 505

### 5 Conclusion

By combining direct images, mass measurements and 507 FEM analysis we offer an alternative picture for the evap-508 oration process in narrow glass channels. The drying dy-509 namics are set by the shape of the air/water interface 510 and is localised close to the free surface until the last 511 stage where the channel is covered by a very thin film. 512 Accordingly slight changes of the entrance geometry and 513 water distribution at the entrance significantly modify the 514 drying rate. This is contrary to the classical picture that 515

Fig. 9. Simulations of evaporation. (a) Evaporating flux F along the air/water interface parallel to the axis in the configuration where  $\alpha = 90^{\circ}$ . The dotted line emphasizes the exponential decay. (b) Dependence of the drying rate J on the simplified interfacial shape, where the side layer entrance angle  $\alpha$  changes, as shown in the inset. By normalizing the drying rate using  $J_1$ , the rate for thin films, and the aspect ratio, w/W, five curves corresponding to different w/W collapse. (c) Dependence of the drying rate on the saturation for the two scenarios, where the drying rate is normalized by  $J_{CRP}$  which is the rate during the CRP. The solid curve represents decreasing side layer thickness, w, and the dashed curve represents the decreasing entrance angle  $\alpha$  of the side layer.

viscous losses are sufficiently large to cause evaporation to
 proceed via diffusion from a penetrating drying front.

The existence of a thick film is due to capillary equilib-518 rium in our geometry and a similar water distribution may 519 occur in cracks, wedge and microfluidics channels with a 520 spacing of high aspect ratio. Indeed in this case, a small 521 variation of spacing is enough to obtain two thick water 522 layers in the channel edges instead of thin films in the 523 four corners of the section. Water remains at the channel 524 entrance; the viscous pressure drop needs to be small com-525 pared to the capillary pressure to provide water to the free 526 surface fast enough regarding the external demand. The 527 same process takes place in a real porous media. At the 528 free surface the evaporative flux  $\psi$  is constant in the CRP. 529 Capillarity drives the flow of water to the surface where 530 evaporation occurs and scales with the Laplace pressure 531  $p_{\rm c} = \gamma/a$ , where a is the typical pore size. Viscous dis-532 sipation can be written as  $\Delta p_{\rm visc} = \mu \psi L/k$  (with k the 533 permeability) and as long as  $\Delta p_{\rm visc} \ll p_{\rm c}$ , water flow to 534 the surface to compensate evaporation. In complex porous 535 structures, films are usually thick enough to allow water 536 flow [15, 16] and to transport elements towards the free 537 surface [17, 18]. As water content decreases, films become 538 thinner and viscous dissipation increases. When viscous 539

dissipation is too high  $\gamma/a < \mu \psi L/k$ , the water evaporat-540 ing close to the free surface is not replaced and a drying 541 front invades the porous medium. Hence the evaporation 542 rate diminishes because water needs to diffuse from drying 543 front to the free surface. In our geometry viscous dissipa-544 tion is always small compared to capillary pressure and 545 we demonstrate that the Falling Rate Period does not re-546 quire a receding front. The general process of FRP is not 547 invalidated by our results but we show a mechanism that 548 may apply to some configurations of porous media where 549 it is possible to decrease the drying rate as capillarity is 550 still dominant. Some channel characteristics can be con-551 verted to those used for porous media like the permeability 552 or the capillary pressure; but geometrical parameters (as-553 pect ratio) are not clearly defined in a porous structure. 554 Two parameters can be identified: the wettability of the 555 solid for the shape of the air/water interface and the ra-556 tio of the diffusion length to the pore size for the drying 557 conditions. 558

The wetting angle is an important parameter of drying in a porous media, it modifies the amplitude of the capillary forces and thus of the pumping mechanism providing water to the free surface. Moreover the contact angle sets the water distribution at capillary equilibrium as

#### Page 10 of 10

the porous medium desaturates, high contact angle limits 564 water preference for corners and small pores which may 565 reduce the drying rate by increasing diffusion length. The 566 pore size also impacts the capillary forces. Moreover the 567 drying rate may decrease with the wetted fraction of the 568 free surface. These results suggest that, as capillary ef-569 fects are dominant and wet patches are sparse in com-570 plex porous structure, the evolution of the exact shape of 571 the liquid/air interface will govern the evaporation rate. 572 We thus conjecture that in certain cases the variations in 573 pore shape of a porous medium close to the free surface 574 can strongly influence drying rate. This insight may help 575 design porous structures with desired evaporation rates. 576

#### 577 Author contribution statement

EK carried out the experiments. EK, SAK, PC developed the models. All authors designed the experiments,
discussed the results and wrote the manuscript.

We thank T. Kodger for experimental assistance and helpful discussions; A. Vian for the SEM images.
