(Received xx; revised xx; accepted xx)

1 The so-called moist-convective shallow-water model, which incorporates moist convection  
 2 in a simple albeit self-consistent way is used to analyse how intense localized vortices,  
 3 with distributions of horizontal velocity and relative vorticity close to those observed  
 4 in tropical cyclones (TC), evolve and interact with topography on the beta-plane at low  
 5 latitudes. Instabilities of such TC-like vortices are studied first in the  $f$ - plane approxima-  
 6 tion, and their development , interplay with beta-gyres and the role they play in vorticity  
 7 redistribution and intensification are then analysed along the vortex trajectories on the  
 8 beta- plane, both in dry and moist-convective environments. Interactions of the vortices  
 9 with an idealized topography in the form of zonal and meridional ridges and islands of  
 10 elliptic form and the role of moist convection in these processes are then investigated,  
 11 revealing rich vortex-dynamics patterns. The results can be helpful in crude analyses and  
 12 predictions of the evolution of the barotropic component of TC, of their trajectories over  
 13 the ocean and during landfall and of related condensation/precipitation patterns.

 15 vention, Beta-plane, Vortex- Topography Interaction.

---

## 16 1. Introduction

17 Understanding and predicting the structure and trajectories of tropical cyclones  
 18 (TC) are, obviously, tasks of utmost practical importance. Due to complexity  
 19 of the related phenomena, simplified models are traditionally used to gain an  
 20 understanding of the fundamental dynamical properties of TC. The vertical  
 21 structure of TC is the first to be simplified in such models. Let us mention in this  
 22 context the pioneering papers by [Ooyama \(1964, 1969\)](#) and [Charney and Eliassen](#)  
 23 [\(1964\)](#) where two-layer models of the tropical atmosphere were introduced in  
 24 order to describe TC. Such models continue to be used, e.g. ([Jones et al. 2009](#)).  
 25 An even more drastic simplification of the vertical structure leads to purely  
 26 two-dimensional (2D), or quasi- 2D shallow water type models, which helped

† Email address for correspondence: zeitlin@lmd.ens.fr

to understand the instabilities and changes of the horizontal structure of TC during their lifecycle. For example, 2D Euler equations were used in (Schubert et al. 1999; Kossin and Schubert 2001; Menelaou et al. 2012) to explain the formation of so-called meso-vortices in the vicinity of the TC cores. Switching to shallow-water models (Hendricks et al. 2014; Schubert et al. 2016; Lahaye and Zeitlin 2016) allows us to include inertia-gravity waves and related radiative instabilities in the picture. Let us emphasize that instabilities of TC could be captured already in the adiabatic, “dry” models (Schubert et al. 1999). However, as is well known, moist convection is an essential ingredient of the TC dynamics, see the review of (Montgomery and Smith 2017). It can be included in shallow water models in the simplest way as a sink in the mass equation, e.g. Schubert et al. (2016), following the seminal ideas of Matsuno (1966) and Gill (1982b). A more systematic, although following the same philosophy method to include moisture, condensation, and related latent heat release was applied in the moist-convective rotating shallow water (mcRSW) model, respectively, in one- and two-layer versions in (Bouchut et al. 2009) and (Lambaerts et al. 2011). The mcRSW models were recently applied to the analysis of instabilities of TC-like vortices in (Lahaye and Zeitlin 2016; Rostami and Zeitlin 2018). It should be emphasized that instabilities of TC are usually studied in the  $f$ -plane approximation, for the simple reason that in order to conduct a standard stability analysis, one should start from a stationary state, which is not the case of monopolar vortices on the  $\beta$ -plane.

In the following, we continue the long tradition of shallow-water modelling of TC by using the mcRSW, which allows us to incorporate, in a minimalistic way, the dynamical effects of the moist convection, in particular the related enhancement of cyclonic vorticity. We also rely on the fact that including the topography in shallow-water models is easy and computationally friendly. We thus study the evolution and trajectories of the TC-like vortices over the ocean and their landfall in the beta-plane approximation with an idealized topography, centring the beta-plane at a low latitude, and using crude parameterizations of condensation and evaporation, which are simplified as much as possible. We show that, surprisingly, already such a rudimentary version of the model captures well many of the observed, or simulated in “big” models, characteristics of the behaviour of real-life TC. It also allows us to understand some of their basic dynamical properties, and to make rough predictions of trajectories. Needless to say that, by construction, the model obtained by vertical averaging is able to reproduce, in a coarse way, only the large-scale barotropic features of TC.

In addition to their tentative utility in the applications mentioned above, the results presented below reveal some previously unknown, or not sufficiently investigated, facts in the domain of vortex dynamics proper, such as instabilities and trajectories of localized vortices of high intensity on the beta-plane, or interactions of such vortices with the topography.

The paper is organized as follows. In Section 2 we present the model, with short explanations, and discuss its hurricane-like vortex solutions, which are considered as proxies of TC throughout this study. In Section 3 we present the results of the linear stability analysis of such vortices on the  $f$ -plane, analyse how these

instabilities are modified on the  $\beta$ - plane, and study their influence, along with the moist convection, upon trajectories of the vortices. Section 4 is devoted to a study of interactions of TC -like vortices with idealized topography and coasts (landfall), both in adiabatic and moist-convective environments, and the influence of these interactions on their trajectories and intensities. Section 5 contains a summary of the results and conclusions.

## 2. The moist-convective rotating shallow water model (mcRSW) and hurricane-like vortices

### 2.1. The mcRSW model, a reminder

A systematic derivation from first principles of, respectively, one- and two-layer versions of the mcRSW model was given in (Bouchut et al. 2009) and (Lambaerts et al. 2011). Let us recall that the standard shallow -water model of the atmosphere can be obtained by vertical averaging of the hydrostatic primitive equations in the pseudo-height pressure coordinates, e.g. (Zeitlin 2018). Moist convection can be included in the model by adding a vertically integrated specific humidity with a condensation sink, which is then linked to convective fluxes of mass and momentum using Lagrangian conservation of the (linearized) equivalent potential temperature. For our purposes below the simplest one-layer version of the mcRSW model with the addition of a source of moisture representing evaporation, as described in (Lahaye and Zeitlin 2016; Rostami and Zeitlin 2017), and an incorporated topography will be sufficient. No explicit dissipation of any kind is included in the model at this stage, see the explanations below. The equations of this version of the model are:

$$\begin{cases} \partial_t \mathbf{v} + \mathbf{v} \cdot \nabla \mathbf{v} + f(y) \hat{\mathbf{z}} \wedge \mathbf{v} = -g \nabla h, \\ \partial_t h + \nabla \cdot [\mathbf{v}(h - b)] = -\gamma C, \\ \partial_t Q + \nabla \cdot (Q \mathbf{v}) = -C + E. \end{cases} \quad (2.1)$$

Here  $x$  and  $y$  are the zonal and meridional coordinates on the tangent plane,  $\nabla = (\partial_x, \partial_y)$ ,  $\mathbf{v} = (u, v)$ ,  $u$  and  $v$  are the zonal and meridional components of velocity, respectively,  $h$  is geopotential height (thickness),  $b(x, y)$  is the topography,  $f(y)$  is the Coriolis parameter, which is constant  $f = f_0$  in the  $f$ -plane approximation, and is equal to  $f = f_0 + \beta y$  in the  $\beta$ -plane approximation, and  $\hat{\mathbf{z}}$  is the unit vertical vector;  $Q \geq 0$  is specific humidity integrated over the air column,  $\gamma$  is a parameter depending on the underlying stratification,  $C$  is the condensation sink and  $E$  is the surface evaporation source of moisture. They are parametrized as follows:

$$C = \frac{Q - Q^s}{\tau} \mathcal{H}(Q - Q^s), \quad E = \alpha \frac{|\mathbf{v}|}{|\mathbf{v}_{max}|} (Q^s - Q) \mathcal{H}(Q^s - Q). \quad (2.2)$$

Here,  $Q^s$  is a saturation threshold, which can be taken to be constant, as was the case in the early papers on mcRSW. Its dependence on pressure anomaly can be readily included, cf. (Bouchut et al. 2009), which we will do below. In principle, the evaporation threshold could be chosen to be different from  $Q^s$ , as the evaporation, physically, does not take place through the whole air column.

110 We take it to be the same in the crudest variant of the model, in order to avoid  
 111 the proliferation of free parameters. The formula for the condensation in (2.2) is a  
 112 column-averaged version of the standard Betts-Miller parameterization, which is  
 113 used in general circulation models;  $\tau$  is the relaxation time, which is of the order  
 114 of several hours in the tropical atmosphere. The parameterization of evaporation  
 115 in (2.2) uses the standard bulk formula, cf. e.g. (Katsaros 2001), which is of  
 116 use in hurricane modelling (Cronin and Chavas 2019), where we renormalized  
 117 the transmission coefficient by  $|\mathbf{v}_{max}|$ , the maximum value of velocity over the  
 118 domain, i.e. the maximum wind in the hurricane-like vortices we consider, to get  
 119 the non-dimensional parameter  $\alpha$  regulating the intensity of evaporation. This is  
 120 a free parameter, the only one representing processes in the unresolved boundary  
 121 layer in the present formulation of the model, its value in the simulations will be  
 122 given below;  $\mathcal{H}(\dots)$  denotes the Heaviside (step-) function, which accounts for the  
 123 switch character of condensation and evaporation. As is natural in the context of  
 124 TC modelling, we consider the vortex motion mostly over the ocean, where  $b \equiv 0$ ,  
 125 and the bulk formula for evaporation (2.2) is well adapted. In the regions where  
 126  $b \neq 0$ , which correspond to continental surfaces, the properties of evaporation  
 127 change, and this parametrization should be changed. We just switch off the  
 128 evaporation in such zones, as a first approach.

129 By setting  $\gamma = 0$ ,  $\alpha = 0$ , and  $\tau \rightarrow \infty$  which, physically speaking, means  
 130 that the time scale of the dynamical processes in question is much less than  $\tau$ ,  
 131 we get the standard adiabatic (“dry”) rotating shallow water equations, with  
 132 the addition of a passive scalar - the moisture field which decouples from other  
 133 variables and is simply advected by the flow. Notice that in the simplest version  
 134 of the model (2.1) the condensed water vapour just drops off the system. In  
 135 this sense condensation and precipitation are synonymous. Precipitable water,  
 136 precipitation and vaporization can be introduced into the model, following the  
 137 same approach as for the inclusion of water vapour and condensation in (2.1),  
 138 giving an “improved” mcRSW (Rostami and Zeitlin 2018), which we will not be  
 139 using below, again, for simplicity.

140 A general analysis, with necessary benchmarks, of the fundamental properties of  
 141 the system (2.1), and of the parent two-layer model, including the conservation  
 142 laws and energy budget, can be found in the above-cited papers. We should  
 143 only stress here that in the absence of evaporation the moist enthalpy  $m =$   
 144  $h - b - \gamma Q$  is locally conserved, as can be easily seen by combining the second  
 145 and the third equations in (2.1). The conservation of this quantity replaces the  
 146 mass conservation in the “dry” RSW model and, like  $h$  in the latter case,  $m$   
 147 should remain positive, otherwise the phase velocity of the “moist” waves becomes  
 148 imaginary, cf. (Bouchut et al. 2009). This imposes a constraint to be respected in  
 149 numerical simulations. Another important variable for analysis and diagnostics  
 150 quantity is potential vorticity (PV), which is a Lagrangian invariant of the “dry”  
 151 system in the absence of dissipation

$$(\partial_t + \mathbf{v} \cdot \nabla)q = 0, \quad q = \frac{\zeta + f(y)}{h - b}, \quad (2.3)$$

152 where  $\zeta = \partial_x v - \partial_y u$  is relative vorticity. In the presence of condensation, but

153 without evaporation, it is the “moist” PV

$$q_m = \frac{\zeta + f(y)}{h - b - \gamma Q}, \quad (2.4)$$

154 which is a Lagrangian invariant of the “moist” system. In the presence of evap-  
 155 oration the moist PV is not conserved, as can be straightforwardly deduced from  
 156 (2.1):

$$(\partial_t + \mathbf{v} \cdot \nabla)q_m = \gamma \frac{q_m}{h - b - \gamma Q} E. \quad (2.5)$$

157 The term on the right-hand side can be a source or a sink of PV, depending on the  
 158 sign of  $q_m$ . A dissipation, which is absent in (2.1), but which appears implicitly  
 159 in numerical simulations due to various discretization procedures, also introduces  
 160 a local source, or a local sink of the moist PV, depending on the properties of  
 161 the underlying vorticity field. Numerical simulations with the set of equations  
 162 (2.1) that we present below were performed using a second-order high-resolution  
 163 well-balanced finite-volume scheme (Bouchut 2007) in a rectangular domain with  
 164 sponges at the boundaries, which allows us to mostly evacuate fast inertia-gravity  
 165 waves generated by various dynamical processes. No explicit dissipation has  
 166 been added. As was shown in previous works with well-balanced finite-volume  
 167 numerical schemes for shallow-water models, the numerical dissipation, globally,  
 168 mimics the Newtonian one, being concentrated in the zones of high spatial  
 169 gradients. The dependence of the saturation threshold on the pressure anomaly,  
 170 which is proportional to  $\eta = h - H_0$ , where  $H_0$  is the mean value, was taken in the  
 171 form  $Q^s = Q_0^s e^{-0.3\eta} \approx Q_0^s (1 - 0.3\eta)$ , cf. Bouchut et al. (2009). The resolution and  
 172 the domain size varied depending on the dynamical processes under investigation,  
 173 see below. The values of parameters  $\alpha$ ,  $\gamma$ , and  $Q_0^s$  are *ad hoc* at this level, while  
 174 the value of  $\tau$  is taken to be several time steps of the code, to be consistent with  
 175 its physical value, with the scaling we use below. However,  $\gamma$  can be absorbed  
 176 into  $Q$ , with simultaneous renormalization of  $\tau$  and, hence, can be set to be one  
 177 without loss of generality;  $\alpha$  can be also absorbed in  $Q$ . With the fixed value  
 178 of  $\gamma$  we take it to be equal to 0.15, to be consistent with previous simulations  
 179 and benchmarks. We should say that this choice is consistent with the empirical  
 180 value  $\sim 10^{-3}$  of the dimensional transmission coefficient in the bulk evaporation  
 181 formula (Katsaros 2001), which is also used in hurricane modelling (Cronin and  
 182 Chavas 2019), taking into account that vertical integration and renormalization  
 183 by  $|\mathbf{v}_{max}|$ . In all simulations below the initial  $Q$  was uniform, and close to the  
 184 saturation value.

185 Let us comment on the property of the system of losing mass whenever the  
 186 condensation is switched on, and the related loss of the “dry” energy  $E_d =$   
 187  $\int dx dy \left( (h - b) \frac{\mathbf{v}^2}{2} + g \frac{h^2}{2} \right)$  (Bouchut et al. 2009). This means that the system  
 188 should be considered as a limit of an infinitely thick upper layer of a two- (or more)  
 189 layer system, with standard mass and energy budgets (Lambaerts et al. 2011).  
 190 As was already mentioned in (Bouchut et al. 2009), an obvious way to restore  
 191 the mass conservation is radiative relaxation, which can be straightforwardly  
 192 introduced in the present model, if necessary, as was done, e.g. in (Rostami et al.

193 2018). We, however, will refrain from doing this for two reasons, again to avoid  
 194 a multiplication of adjustable parameters. The first reason is that *de facto* in  
 195 the simulations presented below the overall mass loss is less than a tenth of  
 196 a per cent of the initial mass. Notice that the above-mentioned dependence of  
 197  $Q^s$  on pressure anomaly prevents an excessive mass loss. The second is that  
 198 the reasonable radiative relaxation time, taking into account that the model, by  
 199 construction, applies to large-scale horizontal motions, would be a global climate  
 200 relaxation scale of the order of couple months, e.g. (Cronin and Emanuel 2013)  
 201 and references therein. Even if we consider the relaxation scale of an individual  
 202 hurricane, which is estimated as 40–50 days, cf. e.g. (Chavas and Emanuel 2014),  
 203 the typical time scales of dynamical processes we consider and the duration of  
 204 the simulations presented below are of the order of days, so the influence of such  
 205 relaxation on the results is quite limited, which we checked in sample simulations.  
 206 As should be clear already from (2.2), we purposely do not use any detailed  
 207 parameterization of the boundary layer, although such parameterizations exist  
 208 in shallow-water models (Schecter and Dunkerton 2009). Along the same lines  
 209 as evaporation, a bulk formula for the surface drag can be also straightforwardly  
 210 incorporated in (2.1). We do not introduce it either for the reasons explained  
 211 below. Finally, we should say that there is a way to improve the model by  
 212 allowing for horizontal variations of the mean potential temperature, which gives  
 213 the possibility of representing not only the convective mass flux but also the  
 214 heating due to the latent heat release, as was proposed in (Bouchut et al. 2009)  
 215 and recently realized in (Liu et al. 2020). We leave the use of such an ameliorated  
 216 model for a future work.

## 2.2. Hurricane-like vortices in mcRSW

217  
 218 We first construct exact stationary-vortex solutions of the mcRSW equations  
 219 in the  $f$ -plane approximation. They will be later used as initial conditions for  
 220 simulations on the  $\beta$ - plane. To this end, we rewrite the equations of the one-  
 221 layer mcRSW on the  $f$ -plane in polar coordinates  $(r, \theta)$ :

$$\begin{cases} \frac{d\mathbf{v}}{dt} + \left(f_0 + \frac{v}{r}\right) \hat{\mathbf{z}} \wedge \mathbf{v} + g\nabla h = 0, \\ \partial_t h + \frac{1}{r} (\partial_r(rhu) + \partial_\theta(hv)) = -\gamma C \\ \partial_t Q + \frac{1}{r} (\partial_r(rQu) + \partial_\theta(Qv)) = -C + E, \end{cases} \quad (2.6)$$

222 where  $\mathbf{v} = (u \hat{\mathbf{r}}, v \hat{\boldsymbol{\theta}})$  is the velocity in polar coordinates, and the Lagrangian  
 223 derivative is  $\frac{d}{dt} = \frac{\partial}{\partial t} + u\partial_r + \frac{v}{r}\partial_\theta$ . The main observation is that, in the absence  
 224 of evaporation, the axisymmetric azimuthal velocity  $v(r)$  and thickness  $h(r)$  in  
 225 cyclo-geostrophic equilibrium

$$\frac{v^2}{r} + f_0 v = g \partial_r h, \quad (2.7)$$

226 at zero radial velocity  $u = 0$ , and arbitrary constant or azimuthally symmetric  
 227  $Q(r) \leq Q^s$  give an exact solution of (2.6). In a sense, such a solution is an RSW  
 228 analogue of “dry” tropical cyclones discussed in the literature, cf. (Cronin and  
 229 Chavas 2019) and references therein. In the presence of evaporation, in order

to provide an exact solution,  $Q$  should stay at the evaporation threshold, i.e.  $Q = Q^s$ , with the choice of the threshold made above. Staying at the evaporation threshold corresponds to the immediate relaxation limit, where the condensation  $C = -Q^s \nabla \cdot \mathbf{v}$  (Bouchut et al. 2009). With  $E = C$ , and constant  $Q^s$  the axisymmetric divergenceless configurations in this limit are, thus, exact solutions of (2.6).

Coming back to the discussion of extra terms in the mcRSW equations in Section 2.1, we see that adding to the right-hand side of the thickness equation the global radiative relaxation term of the form  $-\frac{h-H_0}{\tau_r}$  with a large, as explained above, relaxation time  $\tau_r$ , where  $H_0$  is the non-perturbed thickness, would lead to a slow dissipation of the vortex, and of all of its perturbations, while a relaxation to an equilibrium profile verifying (2.7) does not affect the solution itself but will slowly damp the perturbations. Adding a bulk surface drag of a standard form  $-K(|\mathbf{v}|\mathbf{v})$  to the right-hand side of the momentum equation would lead to a spindown of the vortex solution. In what follows we are interested in the long-time influence of the beta-effect and topography on the intense hurricane-like vortices, so to maintain their intensity, and mimic the real-life TC, we will not include these terms in the simulations below. Needless to say that the full thermodynamics of real-life TC cannot be captured in mcRSW, so the vortices we consider are dynamical proxies of these latter.

Realistic radial profiles of azimuthal velocity and pressure of TC - like vortices can be obtained by piecewise-constant, or smoothed piecewise-constant distributions of relative vorticity (Schubert et al. 1999; Nolan and Montgomery 2002; Hendricks et al. 2014; Lahaye and Zeitlin 2016). For many purposes it is, however, convenient to have an analytic formula for the azimuthal velocity in terms of smooth functions. We use the following expression for the non-dimensional azimuthal velocity  $V(r)$  of the vortex as a function of non-dimensional radius  $r$  from the centre, which we will call the “*abc*” profile:

$$\bar{V}(r) = (r - r_0)^a e^{-c(r-r_0)^b}, \quad r > r_0, \quad a, b, c > 0 \quad (2.8)$$

where  $a$ ,  $b$ ,  $c$  and  $r_0$  are parameters for which we will use the two sets of values given in Table 1. The profile (2.8) has been already used in our studies of planetary jets and vortices (Rostami et al. 2017, 2018). Corresponding non-dimensional radial profiles of azimuthal velocity and relative vorticity  $\zeta(r)$  are given in figure 1, together with those of non-dimensional thickness anomalies recovered from (2.7). The profile in the upper panels of the figure has a wide region of small negative vorticity beyond the radius of maximum wind (RMW) while the profile at the lower ones has a steeper ascending branch before the RMW and a slower descending trend out of it, which is close to velocity profiles in the observations of TC (Mallen et al. 2005), but leads to non-zero circulation far from the vortex. The results of numerical simulations initialized with these two profiles turn out to be similar. In order to have direct control of the amplitude of the velocity, we introduce its non-dimensional amplitude  $\epsilon$  and renormalize  $\bar{V}(r)$  as follows:

$$\bar{V}(r) \rightarrow V(r) = \epsilon \frac{\bar{V}(r)}{\max|\bar{V}(r)|}. \quad (2.9)$$

TABLE 1. Parameters of the numerical experiments presented below. *ID*: identification of the experiment. *MC*: moist-convective environment, *D*: adiabatic environment. Initial water vapour distribution is  $Q^s - 0.01$ , where  $Q^s = 0.7$  is the saturated value. In all experiments  $r_0 = 0.1$ ,  $c = 14$ ,  $\alpha = 0.15$ .

<i>ID</i>	<i>D1</i>	<i>MC1</i>	<i>D3</i>	<i>MC3</i>	<i>Dbis1</i>	<i>MCbis1</i>	<i>Dbis3</i>	<i>MCbis3</i>	<i>Dbis4</i>	<i>MCbis4</i>

FIGURE 1. Profiles of thickness with indicated Chebyshev points which are used for discretization (*left panels*), and velocity and relative vorticity (*right panels*) of TC-like vortices in RSW. The most unstable mode of the velocity profile in the upper row (*ID* : *D3*) has azimuthal wavenumber 2, and that of the lower row (*ID* : *Dbis3*) has azimuthal wavenumber 3.

271 As is clear from (2.8) the “*abc*” profile is placed at a distance  $r_0$  from the origin.  
 272 It is matched at  $r_0$  with a linear velocity profile in the interval  $[0, r_0]$ , in a way  
 273 to reproduce the observed approximately constant vorticity cores of TC, and to  
 274 have overall continuous velocity and vorticity.

275 The velocity scale  $U = 200$  m/s and the horizontal scale  $L = 400$  km, which is  
 276 typical for TC, are used for non-dimensionalization. The time scale is the vortex

277 turnover time  $T = L/U \approx 0.5\text{h}$ . As already said, we are working in the tangent  
 278 plane approximation. Being motivated by TC, we place our tangent plane at  
 279 a low latitude,  $15^\circ\text{N}$ , which corresponds to  $f_0 = 3.7643 \cdot 10^{-5}\text{s}^{-1}$ . The non-  
 280 dimensional  $\bar{f}_0 = Lf_0/U \approx 7.5 \cdot 10^{-2}$ , which is, in fact, the inverse global Rossby  
 281 number ( $Ro$ ) constructed from the scales given above. We, however, will be using  
 282 another definition of the Rossby number:  $Ro = V_{\max}/f_0L_{\max}$ , where  $V_{\max}$  is  
 283 the maximum of azimuthal velocity (maximum wind), and  $L_{\max}$  is the radius of  
 284 maximum wind (RMW) which is traditional in the TC literature, e.g. (Lahaye and  
 285 Zeitlin 2016). All of the vortices in the experiments presented in Table 1 have large  
 286 Rossby numbers. We, however will call below those with  $Ro = (10.37, 14.5, 19.3)$   
 287 'strong', and the other ones 'weak', bearing in mind the TC nomenclature. In the  
 288 (quasi-) barotropic mCRSW model, we choose  $H_0 = 8.5\text{km}$  as the vertical scale.

289 With the above-described scaling the non-dimensional equation for the radial  
 290 velocity in the  $f$ -plane approximation, which follows after non-dimensionalization  
 291 from (2.6), becomes

$$-\frac{du}{dt} + \frac{v^2}{r} + \bar{f}_0 v = \frac{\lambda}{Fr^2} \partial_r \eta. \quad (2.10)$$

292 We introduced here a non-dimensional amplitude  $\lambda$  of the thickness anomaly  
 293  $h = H_0(1 + \lambda \eta)$ , where  $H_0$  is the mean thickness, and the Froude number  $Fr =$   
 294  $U/\sqrt{gH_0}$ . As in (Lahaye and Zeitlin 2016) we will be assuming in what follows  
 295 that  $\lambda/Fr^2 \sim 1$ . The cyclo-geostrophic equilibrium (2.7) between  $V(r)$  and the  
 296 corresponding thickness profile  $H(r)$  in non-dimensional terms becomes

$$\frac{V^2}{r} + \bar{f}_0 V = H'(r), \quad (2.11)$$

297 where the prime here and below denotes an ordinary derivative with respect to  
 298  $r$ . The thickness profile for a given  $V(r)$  is thus straightforwardly recovered from  
 299 (2.11) by taking the primitive of the left-hand side. For the "abc" profile, with  
 300  $r_0 = 0$  we obtain

$$H(r) = 1 - \bar{f}_0 \frac{\epsilon}{b v_{max}} c^{-\frac{a+1}{b}} \Gamma\left(\frac{a+1}{b}\right) G\left(c r^b, \frac{a+1}{b}\right) - \frac{\epsilon^2}{b v_{max}^2} (2c)^{-\frac{2a}{b}} \Gamma\left(\frac{2a}{b}\right) G\left(2c r^b, \frac{2a}{b}\right), \quad (2.12)$$

301 where  $v_{max} = \max|\bar{V}(r)|$ ,  $G(x, a) = [1/\Gamma(a)] \int_x^\infty t^{a-1} e^{-t} dt$  and  $\Gamma$  denotes the  
 302 gamma function.

### 303 3. Instabilities of hurricane-like vortices and their evolution along the 304 trajectories on the $\beta$ -plane

305 We start our investigation of hurricane-like vortices by a linear stability analysis  
 306 in the adiabatic environment of the vortex solutions on the  $f$ -plane, which were  
 307 described in Sec. 2.2. We then study how these instabilities are modified on the  
 308 beta-plane and in the presence of moist convection, and how these effects influence  
 309 the vortex trajectories.

FIGURE 2. Growth rates of the azimuthal modes  $l = 1, 2, 3$  as functions of the vortex intensity. *Left* and *right* panels correspond to the upper- and lower- row configurations presented in figure 1, respectively.

### 3.1. Instabilities of “dry” TC-like vortices in the $f$ -plane approximation

Analysis of instabilities of the TC-like vortices below follows the lines of (Lahaye and Zeitlin 2016; Rostami and Zeitlin 2017). Taking the “dry” equations (2.6), i.e. switching off the condensation  $C$ , linearizing them around the vortex solution (2.8), (2.11) and looking for solutions in the form of azimuthal normal modes

$$(u, v, \eta) = \text{Re}\{[iu_0(r), v_0(r), \eta_0(r)]e^{i(l\theta - \omega t)}\}, \quad (3.1)$$

we get the following eigenproblem for eigenvalues  $\omega$  and eigenvectors  $[u_0(r), v_0(r), \eta_0(r)]$ :

$$\omega \begin{pmatrix} u_0 \\ v_0 \\ h_0 \end{pmatrix} = \begin{pmatrix} lV/r & (\bar{f}_0 + 2V/r) & -D_n \\ \partial_r V + V/r + \bar{f}_0 & lV/r & l/r \\ \frac{Fr^{-2} + (rH)'}{r} + (Fr^{-2} + H)D_n & \frac{Fr^{-2} + H}{r}l & lV/r \end{pmatrix} \cdot \begin{pmatrix} u_0 \\ v_0 \\ \eta_0 \end{pmatrix}, \quad (3.2)$$

where  $D_n$  is the operator of differentiation in  $r$ , which becomes a differentiation matrix after discretization using the Chebyshev collocation points (Wright 1964), cf. figure 1. Its numerical solution is obtained with the help of the pseudo-spectral collocation method. As the gradient of the vorticity changes sign, cf. figure 1, we expect a barotropic instability, according to the standard criteria, i.e. complex eigenvalues  $\omega = \omega_0 + i\sigma$ , where  $\sigma$  is the growth rate. By obvious reasons, we are mostly interested in the fastest-growing most unstable modes. The results of the numerical stability analysis are presented in figure 2, where the growth rates of the two most unstable azimuthal modes, as well as that of the mode  $l = 1$ , which is important in the following, are plotted as functions of the parameter  $\epsilon$  which controls  $V_{\max}$ , cf. (2.9), for the two configurations of figure 1. We should emphasize that, as it was already stressed in (Lahaye and Zeitlin 2016), the instability is sensitive to the fine details of the vorticity profile. Thus, by increasing the slope of the ascending branch of velocity and vorticity in the vicinity of the core (lower panel of figure 1) the most unstable mode switches from  $l = 2$  to  $l = 3$ . The structure of the unstable modes with  $l = 2$  and  $l = 3$  is presented in figure 3. More details on the stability analysis of TC-like configurations in the framework of mcRSW model, including the dependence of the most unstable

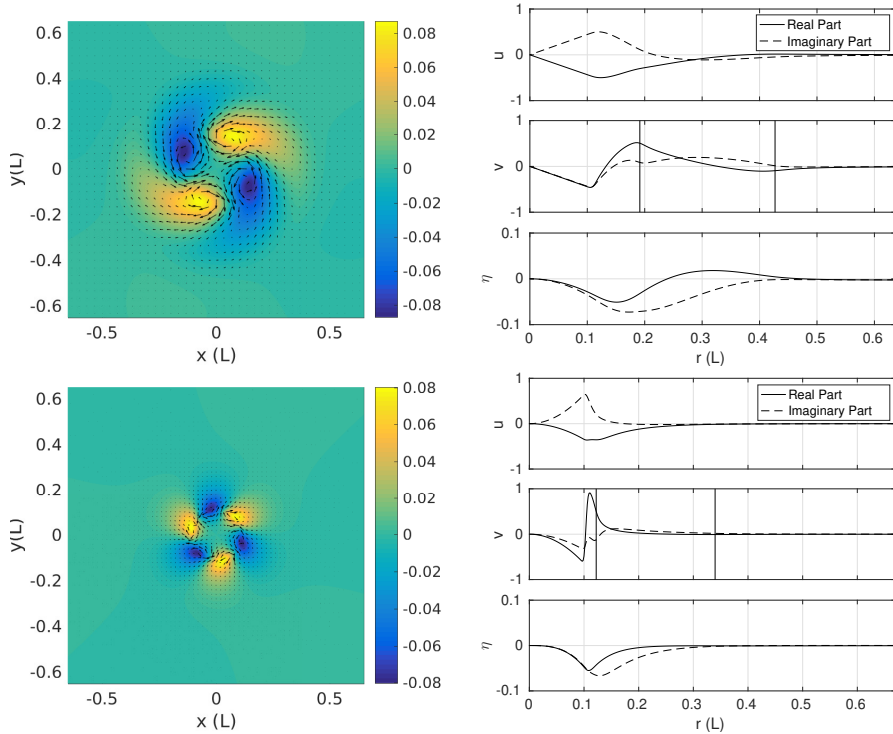

FIGURE 3. Spatial distribution of thickness (colours) and velocity (arrows) (*left column*) and radial dependence of  $u, v, \eta$  (*right column*), with the critical radii indicated by the vertical lines, of the most unstable mode  $l = 2$  of the vortex corresponding to  $ID : D3$ , and of the most unstable mode  $l = 3$  corresponding to  $ID : Dbis3$ .

mode on the RMW can be found in (Rostami and Zeitlin 2018). Let us however, emphasize, that the results above are obtained in the vertically averaged model with the crudest parametrization of condensation and evaporation. Studies of instabilities of hurricanes in the framework of full three-dimensional primitive equations and in cloud-resolving models, with detailed representation of three-dimensional hurricane structure and thermodynamics of the moist air can be found in (Schecter and Montgomery 2007) and (Schecter 2018), respectively.

It is known that the nonlinear evolution of the instability in the  $f$ -plane approximation leads to homogenization of the vorticity in the centre of TC-like vortices, and its intensification, (Schubert et al. 1999; Kossin and Schubert 2001; Rozoff et al. 2009; Hendricks et al. 2014; Lahaye and Zeitlin 2016). This process corresponds to the evolution and different states of TC cores which were found in observations (Mallen et al. 2005). We do not investigate here such evolution on the  $f$ -plane, as in the above-mentioned studies, and pass directly to the  $\beta$ -plane configuration.

### 3.2. Instabilities of TC-like vortices on the $\beta$ -plane, and the influence of beta-gyres

The evolution of intrinsic instabilities of hurricane-like vortices on the  $\beta$ -plane cannot be dissociated from a well and long-time known phenomenon due to the  $\beta$ -effect: development of the so-called beta-gyres (Reznik and Dewar 1994;

353 Sutyryn and Flierl 1994) resulting from the Rossby-wave emission by the vortex.  
 354 Corrections to the process of formation and the characteristics of the beta-gyres,  
 355 initially described in quasi-geostrophic models, were studied in much detail in the  
 356 full RSW model in (Reznik and Grimshaw 2001), although in the small Rossby  
 357 number regime. Due to this phenomenon, the cyclonic vortices start moving in the  
 358 north-west direction in the Northern hemisphere (the so-called beta-drift). The  
 359 influence of the beta-effect upon the trajectories and internal structure of TC-like  
 360 vortices was studied in the barotropic non-divergent model (i.e. 2D Navier-Stokes  
 361 equation on the  $\beta$ -plane) by Chan and Williams (1987); Fiorino and Elsberry  
 362 (1989), and in the shallow-water model by Willoughby (1994).

363 Compared to the previous studies, we have at our disposal a much more  
 364 reliable and higher-resolution simulation tool, and the possibility of including  
 365 the important effects of moist convection. We performed a number of numerical  
 366 experiments on the propagation of TC-like vortices on the  $\beta$ -plane in the  
 367 Northern hemisphere, and development of instabilities, in the “dry” and moist-  
 368 convective configurations displayed in Table 1. A summary of the results, some  
 369 of which we present below, is that the intense vortices are propelled north-  
 370 westward by the beta-gyres, the structure of which is sensitive to the strength  
 371 of vortices, and to the presence, or absence, of moist convection. The meridional  
 372 displacement increases with vortex intensity, and north westward drifting strong  
 373 vortices veer eventually eastward, while at equal intensity the influence of the  
 374 effects of moisture upon the drift is relatively weak. At the same time, the  
 375 asymmetry enhanced by the beta-gyres triggers instabilities which develop in the  
 376 core, leading to formation of secondary “eyewall meso-vortices”, which are well  
 377 documented in the observations of TC, e.g. (Kossin et al. 2002). The formation  
 378 and properties of the meso-vortices are mostly sensitive to the details of the  
 379 vorticity profile and the strength of the parent vortex, and are less sensitive to  
 380 the effects of moisture. During nonlinear evolution, the ring of high PV in the  
 381 vortices with higher  $Ro$  breaks down faster than in those with lower  $Ro$ . The  
 382 eyewall meso-vortices generated by this process can then wander inside the eye,  
 383 and eventually merge.

384 We present in figure 4 a comparison of evolution scenarios of weak and strong  
 385 hurricane-like vortices in the moist-convective environment on the beta-plane  
 386 with  $ID\ MC1, MC3$ , respectively. The vortex profile in both cases corresponds  
 387 to figure 1 (upper panels) with the most unstable mode  $l = 2$ , although for the  
 388 weaker vortex the growth rates of modes  $l = 2$  and  $l = 3$  are close, cf. figure  
 389 2. In contrast with the studies of the evolution of vortex instabilities on the  $f$ -  
 390 plane (Lahaye and Zeitlin 2016; Rostami and Zeitlin 2017), the simulations were  
 391 not initialized with a perturbation corresponding to the most unstable mode,  
 392 the instability having been triggered by the asymmetry introduced by the beta-  
 393 gyres. As follows from the figure, the beta-drift is stronger for the stronger  
 394 vortex (see also below), the instability of the core is stronger as well, and the  
 395 secondary eyewall meso-vortices are more pronounced. Their structure at initial  
 396 stages clearly reflects the dominant  $l = 2$  instability of the stronger vortex, and  
 397 a mixture of  $l = 2$  and  $l = 3$  instabilities of the weaker vortex, in agreement with  
 398 the linear stability analysis of Section 3.1. However, the  $l = 1$  mode, whose growth

rate was negligible on the  $f$ - plane, cf. figure 2, exhibits a considerable growth due to the influence of the beta-gyres, as follows from figure 5. The mechanism of intensification in the core region is clear from figure 4: it is due to the merger of meso-vortices. The evolution of weak and strong vortices in the adiabatic (“dry”) environment is qualitatively similar to that of figure 4 (not shown).

An important question is about the role of moisture in the evolution of the intensity of the hurricane-type vortices, cf. (Lahaye and Zeitlin 2016). A comparison of the evolution of the peak PV in adiabatic and moist-convective environments is presented in figure 6. For the weak vortex, the peak “dry” PV is quasi-monotonously decreasing, after a transient growth due to redistribution of PV produced by discretization errors, and related readjustment process. However, this decrease is attenuated by the effects of moisture. For the strong vortex the PV evolution exhibits a period of strong growth associated with the appearance of pronounced meso-vortices (the second from the top panel of the right column in figure 4), and a second period of growth associated with their merger (the third from the top panel of the right column in figure 4), the latter one being significantly enhanced by the moist convection. The non-conservation of the peak PV is due to numerical dissipation, and to the moist convection, if present, but it is rather limited, as the overall change of the peak PV is  $\approx 7\%$  for the weak, and  $\approx 10\%$  for the strong vortex. We thus confirm the result previously obtained in the  $f$ -plane approximation Lahaye and Zeitlin (2016): the evolution of the vortex core instability leads to intensification, and that moist convection substantially enhances this process. The modification of the instability pattern on the beta-plane due to the growing  $l = 1$  mode apparently does not change the overall scenario of intensification.

The structure of the beta-gyres differs for strong and weak (in the sense explained in Sec. 2.2 above) vortices, as follows from figure 7, where their evolution is presented in the moist-convective case, the pattern in the “dry” case being very close. At the initial stages the beta-gyres arise and slowly intensify. The anticyclonic gyre is formed to the north-east and the cyclonic one to the south-west with respect to the vortex core. The centres of the gyres then start to slowly rotate clockwise. Although the individual structure of the beta-gyres is sensitive to initial velocity and vorticity profiles, our results on the initial formation and evolution of the gyres are in global agreement with previous shallow-water modelling of TCs, e.g. (Li and Wang 1994), and also with observational data analyses e.g. (Kim et al. 2009). As time goes on, a Rossby-wave tail develops in the south-eastern sector with respect to the core of the vortex. Initially, the flow between the main vortex and the major gyre is north-westward, but as the gyres rotate this flow turns northward.

Condensation is inherent to the evolution of vortices in the moist-convective environment (Lahaye and Zeitlin 2015; Rostami and Zeitlin 2017). While it is mostly axisymmetric for TC-like vortices in the  $f$ -plane approximation (Lahaye and Zeitlin 2015), this is not the case on the  $\beta$ - plane. We found that the time-averaged condensation pattern is clearly asymmetric with respect to the vortex centre, as follows from figure 8. At the same time, the water vapour distribution roughly follows the beta-gyre structure. As is clear from the figure, the rear-right

FIGURE 4. Comparison of the evolution of weak (*ID* : *MC1*, *left panel*), and strong (*ID* : *MC3*, *right panel*) hurricane-like vortices on the  $\beta$ -plane in moist-convective environment, as seen in the potential vorticity field. Snapshots at  $t = 40, 55, 80, 100[L/U]$ , from top to bottom.

FIGURE 5. Logarithm of the normalized amplitude of the  $l = 1$  component of the azimuthal velocity field calculated in the domain  $r < 0.5$  as a function of time during the evolution of the weak (*left panel*, ID : D1, MC1) and strong (*right panel*, ID : D3, MC3) hurricane-type vortices in “dry” (*solid*) and moist-convective (*dashed*) environment. Vorticity profiles correspond to the upper panel of figure 1.

FIGURE 6. Comparison of the evolution of the maximum of potential vorticity of weak (ID : MC1 *left panel*), and strong (ID : MC3 *right panel*) hurricane-like vortices on the  $\beta$ -plane in the moist-convective (*dashed*) versus “dry” (*solid*) environments.

445 sector, following the vortex motion, is a zone of the highest condensation, while  
 446 the front-left sector is the zone of the lowest condensation. This result strongly  
 447 resembles observations of convection in TCs over the western Pacific during the  
 448 period from 2005 to 2012 (Yang et al. 2016).

### 449 3.3. Trajectories of hurricane-like vortices on the beta-plane and inertia gravity wave 450 emission

451 The above-mentioned north-western drift of cyclonic vortices due to the beta-  
 452 gyres is robust, and can be established already for the point vortices on the  $\beta$ -  
 453 plane (Reznik 1992). In shallow water the drift velocity of low Rossby number vor-

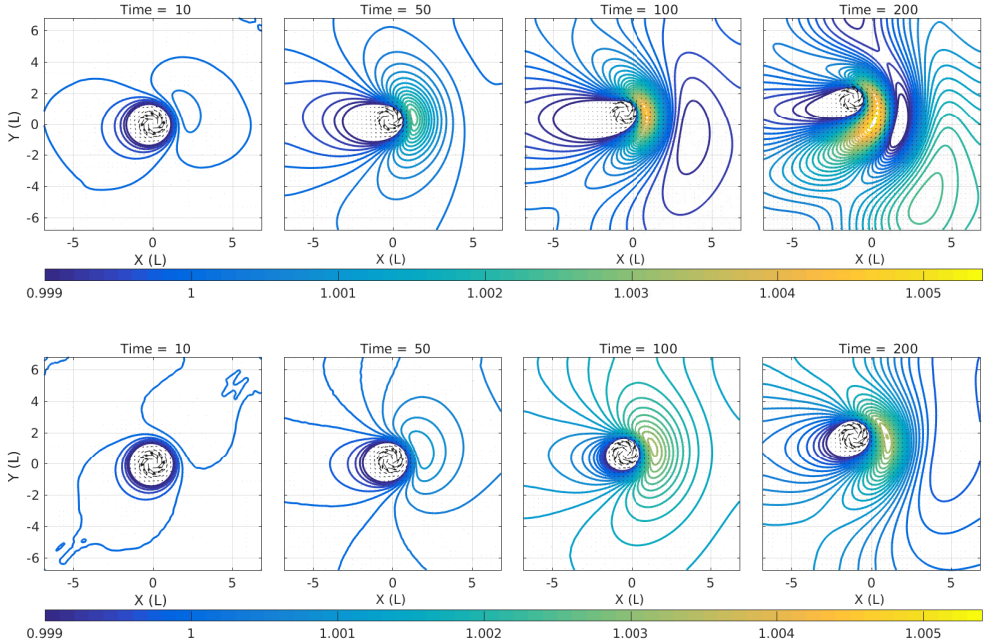

FIGURE 7. Formation of (nonlinear) beta-gyres during the evolution of the weak (*upper panel*, *ID : MC1*), and strong (*lower panel*, *ID : MC3*) hurricane-type vortices in moist-convective environment, as seen in the thickness field beyond the radius of maximum wind.

FIGURE 8. Asymmetric distribution of time-averaged condensation for two hurricane-like vortices with different Rossby numbers. *ID : MCbis1* (*left panel*) and *ID : MCbis3* (*right panel*).

454 tices experiences periodic modulations (Reznik and Grimshaw 2001). As shown  
 455 above, we do observe a pronounced beta - drift of the hurricane-type vortices.  
 456 Trajectories of vortices of different intensity in adiabatic and moist-convective  
 457 environments are displayed in figure 9. The drift velocity in our simulations is  
 458 not uniform, as can be inferred from figure 9, where the points are plotted at  
 459 equal time intervals - for example, vortices slow down while turning north - but  
 460 its variations are not periodic, as in (Reznik and Grimshaw 2001), which is,  
 461 apparently, due to the largely different Rossby numbers.

FIGURE 9. Trajectories of hurricane-like vortices with different Rossby numbers in dry (D) and moist-convective (MC) environments, as defined in Table 1. Time span is from 0 to 315, at the interval 15 [ $L/U$ ].

462 What is important is that we see a clear-cut difference between the behaviour  
 463 of vortices of moderate and strong intensities. While the former follow the  
 464 trajectories predicted in the literature in the no background flow case, e.g.  
 465 (Adem 1956; McWilliams and Flierl 1979; Chan and Williams 1987; Reznik 1992),  
 466 with the moist convection not substantially affecting the trajectory, and “moist”  
 467 meridional velocity being lower than the “dry” one, the latter behave differently.  
 468 Their trajectories are almost straight for a long time, with meridional veloc-  
 469 ities much higher than for moderate -intensity vortices, and “moist” meridional  
 470 velocities higher than the “dry” ones. Remarkably, the trajectories of intense  
 471 vortices turn north, and then north-east at late stages, a behaviour which is  
 472 usually attributed in the observations of TC to the influence of the mean wind,  
 473 although there is none in the present simulations. In order to understand the  
 474 dynamical processes at the origin of these north-east turns we present in figure  
 475 10 the outer structure of an intense vortex at the stage when it starts turning  
 476 northward. As follows from the figure, the main anticyclonic lobe of the associated  
 477 beta-gyre exhibits intensification and significant clockwise displacement. As a  
 478 result, the axis of the dipole which it forms with the main vortex turns north-  
 479 eastwards, which explains the change in the direction of propagation. The rate  
 480 of this rotation of the lobe is higher in the “dry” case, which is consistent with  
 481 the behaviour of respective trajectories in figure 9. The evolution of the pressure  
 482 field in the moist-convective environment is significantly affected by condensation  
 483 accompanied by emission of the inertia-gravity waves (IGW), which explains this  
 484 difference. Both condensation and IGW emission are displayed in the two lower  
 485 panels of figure 10. As follows from figure 11, where we diagnosed the associated  
 486 wave activity, the outward-propagating IGW originating in the vortex core are  
 487 amplified with increasing  $Ro$  in the moist-convective environment. The above-  
 488 described formation, wandering and merger of meso-vortices during the nonlinear

489 evolution of intense TC - like vortices are at the origin of the peaks of the wave  
490 activity.

### 491 3.4. Summary and preliminary conclusions

492 Before including the orographic effects in the next section, let us briefly sum-  
493 marize the above-described results of the simulations of the lifecycle of hurricane-  
494 like vortices on the  $\beta$ - plane. The vortex instabilities, which are identified in the  
495  $f$ -plane approximation, are triggered by the inhomogeneity due to the beta-effect.  
496 Their development leads to formation of the meso-vortices, which subsequently  
497 merge and lead to intensification of the vortex at its core. The larger the Rossby  
498 number of the vortex, the more pronounced are the meso-vortices, and related  
499 processes. At the same time, according to the known mechanism, beta-gyres are  
500 developed in the vicinity of the vortex. They lead to the north-western beta-drift,  
501 which is substantially different for vortices of moderate and strong intensity. In  
502 the latter case, nonlinear evolution and the related change of orientation of the  
503 beta-gyres lead to a change of orientation of the trajectory, which eventually  
504 veers north-eastward. The characteristic vortex-dynamics events described above  
505 (formation and merger of meso-vortices, change of orientation of the beta-gyres)  
506 are accompanied by related bursts of inertia-gravity wave emissions by the vortex.

## 507 4. Interactions of hurricane-like vortices with idealized ridges and 508 islands

### 509 4.1. Preliminaries

510 Changes in structure and intensity of TC travelling over the ocean and en-  
511 counterling coasts (landfall) are of obvious high importance, and there exists an  
512 extensive literature on this subject. On the other hand, interactions of vortices  
513 with topography is a recurrent subject in the oceanographic literature as well.  
514 Most of the theoretical advances in our understanding of vortex evolution in  
515 the presence of topography were achieved using the barotropic non-divergent  
516 model (called the long-wave approximation in oceanography (Gill 1982a)), which  
517 in the context of shallow-water modelling, neglects the deformation of the free  
518 surface. A common approach is based on the asymptotic analysis of the equation  
519 of conservation of PV in this model at small times, for initially axisymmetric  
520 vortex configurations. It was initiated by Adem (1956), and then extended and  
521 developed by many others, e.g. (Smith and Ulrich 1990; Grimshaw et al. 1994;  
522 Richardson 2000). There also exist numerical simulations using the same model  
523 with simple topography profiles on the  $f$ -plane, e.g. (Grimshaw et al. 1994;  
524 Richardson 2000; Hinds et al. 2016), and on the beta-plane (vanGeffen and  
525 Davies 1999), as well as laboratory experiments in rotating tanks (Carnevale  
526 et al. 1991; Flor and Eames 2002). As can be inferred from these studies, e.g.  
527 (Grimshaw et al. 1994; Richardson 2000), a monopolar cyclonic vortex in the  
528  $f$ -plane approximation tends to go first across, and then along the topography  
529 isolines. At the same time, the vortex perturbation generates topographic waves  
530 starting to propagate along the topography isolines (Grimshaw et al. 1994). The  
531 details of the vortex behaviour depend on the parameters of the topography (slope

FIGURE 10. Snapshots of the isobars beyond the radius of maximum wind for the strongest vortex ( $Ro = 19.3$ ) of figure 9 in the “dry” (first row, ID : *Dbis4*) and moist-convective cases (second row, ID : *MCbis4*). Third row: Spatial distribution of condensation corresponding to the second row. Fourth row: Corresponding to the second row convection-coupled inertial gravity waves, as seen in the divergence field. Colour bar is saturated in the core region.  $T = 255, 270, 285, 300 L/U$ .

FIGURE 11. Wave activity measured as the modulus of divergence integrated over the region beyond the radius of maximum wind during the evolution of TC-like vortices with different Rossby numbers in dry and moist-convective environments.  $Ro = 14.5$  (left panel, ID : *Dbis3, MCbis3*),  $Ro = 19.3$  (right panel, ID : *Dbis4, MCbis4*), respectively.

and height), and on the intensity of the vortex. On the beta-plane the situation is more complex because of the simultaneous influence of the beta- and topographic gyres developing around the vortex, and analysis of PV conservation becomes more involved. Yet it helps to interpret the results of numerical simulations, e.g. Zehnder (1993) where numerical experiments with a shallow-water model on the equatorial beta-plane were performed, together with a qualitative theoretical analysis.

Compared to the existing literature on this subject, we have the advantage of being able to use a state-of-the-art high-resolution well-balanced numerical scheme, allowing to represent with high fidelity both the effects of vortex stretching due to deformations of the free surface, and the inertia-gravity and topographic waves, and also to incorporate the effects of moisture, and to study their influence.

#### 4.2. Interactions of hurricane-like vortices with idealized mountain ridges

We start our study of the effects of topography by analysing the interaction of, first, weak and, second, strong vortices, in the sense of section 2.2 with a straight infinite meridional and zonal bumps (idealized mountain ridges). Low ( $b_{max} = 0.1$ ) and high ( $b_{max} = 0.2$ ), in units of  $H_0$ , bumps of Gaussian shape were implemented.

##### 4.2.1. Weak TC-like vortex

In figure 12 we present a comparison of the trajectories of a weak TC-like vortex encountering a low zonal bump in adiabatic and moist-convective environments, and the corresponding evolution of its peak relative vorticity. The recurving of the trajectories observed in the figure is correlated with formation of the topographic gyres discussed in the above-cited literature. They are clearly seen in the upper and middle panels of figure 13, where we present the evolution of relative vorticity, and can be anticipated from the conservation of PV. The recurving and rightward

FIGURE 12. Comparison of the tracks of a weak (*ID: D1, MC1*) TC-like vortex (*left panel*) over a Gaussian ridge with  $b_{max} = 0.1$ , and related evolution of the peak relative vorticity (*right panel*) in “dry” (white dots, solid) and moist-convective (black dots, dashed) environments. Time span from 0 to 495, the interval between consecutive dots is 15  $[L/U]$ .

559 shift start earlier in the moist-convective environment. This is due to the fact  
 560 that it is the moist enthalpy  $h - b - \gamma Q$  which replaces the thickness  $h - b$  in  
 561 the expression of the conserved (in the absence of dissipation and evaporation)  
 562 potential vorticity, cf. (2.4), which means that the effective topography is higher in  
 563 the moist-convective case. The evolution of the peak vorticity is similar in the two  
 564 cases, although the peak vorticity in the moist-convective environment is higher,  
 565 starting from the encounter of the vortex with the ridge, and this difference is  
 566 increasing in time, cf. the right panel of figure 12. This is due to the condensation  
 567 in the vortex core during the crossing, which is clearly seen in the lower panel of  
 568 figure 13, as condensation enhances the cyclonic vorticity. The minimum of the  
 569 peak vorticity at later times, observed in both curves in the right panel of figure  
 570 12 corresponds to the passage by the TC of the topography maximum, and can be  
 571 easily explained in terms of PV conservation: diminishing the denominator in the  
 572 PV (2.3) should be compensated by diminishing the numerator, i.e. diminishing  
 573 the relative vorticity, and *vice versa*. A similar form of trajectory, and of the  
 574 peak vorticity evolution, was reported in vanGeffen and Davies (1999), where  
 575 numerical simulations of monopolar vortex interacting with ridges of various  
 576 orientations were performed in the framework of the “dry” non-divergent model.  
 577 Notice that the overall initial depletion of the relative vorticity is due to the  
 578 meridional propagation which increases the planetary vorticity  $f_0 + \beta y$  in the  
 579 Northern hemisphere which, again, as follows from the PV conservation, should be  
 580 compensated by a decrease in relative vorticity, at constant thickness. The lag of  
 581 this minimum in the moist-convective case is explained by the faster propagation  
 582 speed in the dry case, which can be inferred from the left panel of figure 12.  
 583 Increasing the height of the ridge leads to a slow-down of the weak vortex over  
 584 the ridge, and to a backward motion in the case of meridional ridge, as follows  
 585 from figure 14. We will come back to this phenomenon in the next subsection,  
 586 and concentrate first on the topographic gyre formation, and its interaction  
 587 with the primary vortex and its beta-gyre, which is illustrated by figure 15.  
 588 The figure displays a rich vortex dynamics pattern with several distinguished  
 589 features. A cyclonic topographic gyre arises by the process of enhancement of

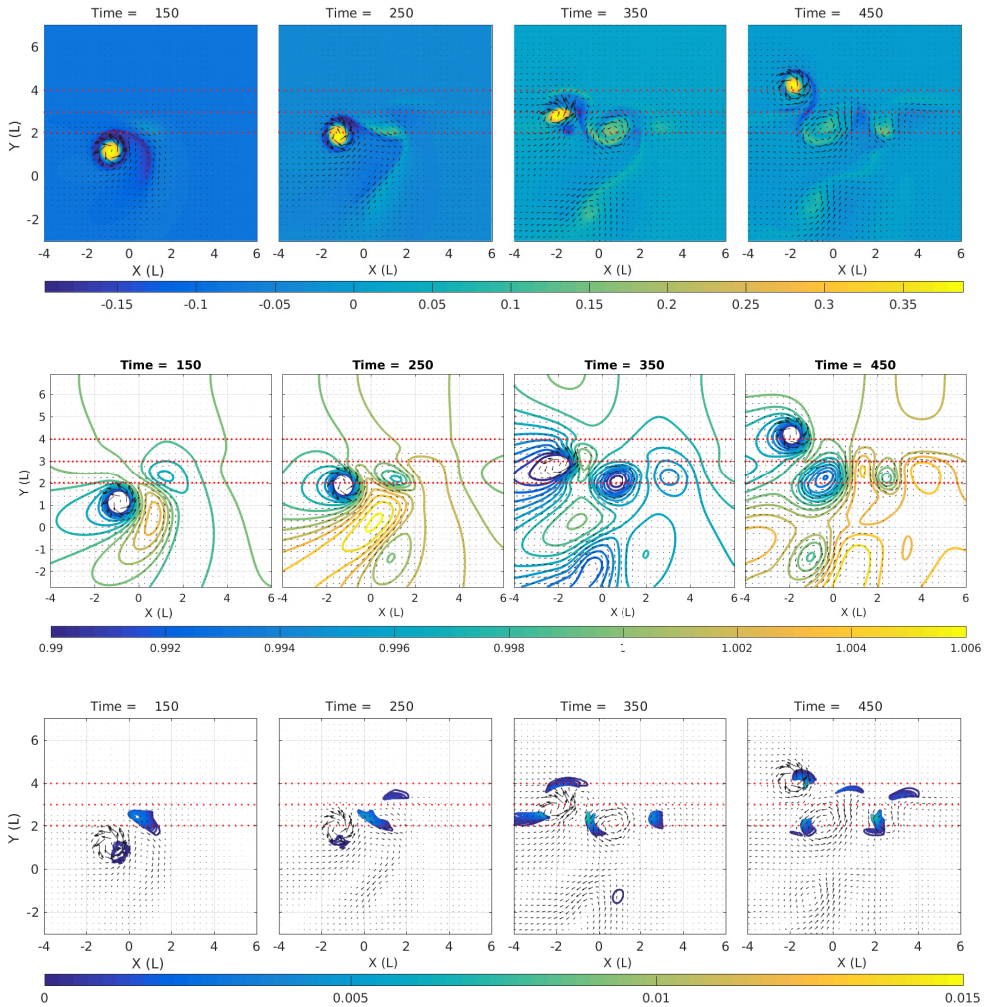

FIGURE 13. *Upper row*: Spatio-temporal evolution of the relative vorticity during the passage of a weak TC-like vortex (*ID : MC1*) over a zonal Gaussian ridge with  $b_{max} = 0.1$  at  $y = 3$ . *Middle row*: Corresponding evolution of  $h$ . *Lower row*: Corresponding evolution of condensation. Horizontal dotted lines indicate the ridge.  $T = 350$  corresponds to the minimum of the relative vorticity in figure 12.

590 the second (cyclonic) lobe of the beta gyre when the TC approaches the ridge. It  
 591 then intensifies. The topographic gyre forms an asymmetric dipole with the rear  
 592 part of the first anticyclonic lobe of the beta gyre, with a tendency of moving  
 593 backward from the ridge along its axis and hence, by conservation of momentum,  
 594 pushing the main vortex in the opposite direction, which can explain the initial  
 595 acceleration of the vortex over the ridge observed in the left panel of figure 14  
 596 (larger distance between the consecutive dots). Recurving of the trajectory is  
 597 due to the deformation and stretching of the anticyclonic vorticity surrounding  
 598 the core, together with that of the near field of the beta-gyre, which leads to  
 599 reorientation of the axis of the vortex dipole which it forms with the main vortex,

FIGURE 14. Trajectories of a weak TC -like vortex ( $ID : D1$ ) (white dots indicating peak vorticity) passing over a zonal (*left panel*) and a meridional (*right panel*) ridges with  $b_{max} = 0.2$  in “dry” environment. Time span is  $[0, 270]$  and time interval between consecutive dots is  $15L/U$ .

600 and hence a change in the direction of propagation. Stalling of the vortex at the lee  
 601 side of the ridge, which is seen at later stages in the same figure is due to formation  
 602 of a tripolar structure, involving the remnants of the main anticyclonic lobe of  
 603 the beta-gyre, the main vortex, and a secondary anticyclonic topographic gyre,  
 604 which arises downslope and westward of the main vortex. Notice the vorticity  
 605 pattern appearing to the right of the main vortex structure. It is related to the  
 606 topographic wave, which is coupled to the cyclonic topographic gyre, and leads  
 607 to the alignment of the latter along the ridge at the later stages - see also below.

#### 608 4.2.2. Strong TC -like vortex

609 Figure 16 represents a counterpart of figure 12 for a strong TC -like vortex  
 610 passing over the ridge with  $b_{max} = 0.2$ . The trajectories in both “dry” and moist-  
 611 convective environments are looping downslope, leading to trapping of the vortex  
 612 by topography. As follows from figure 17, where we present the corresponding  
 613 evolution of relative vorticity in the “dry” case, a cyclonic topographic gyre  
 614 also arises, and forms a dipole with the tail of the anticyclonic beta-gyre lobe,  
 615 as in the case of the weak TC -like vortex above, with a similar acceleration  
 616 effect, cf. figure 16. The recurving of trajectory at the lee side of topography,  
 617 and subsequent looping are similar to the weak vortex case, and are due to a  
 618 secondary anticyclonic topographic gyre, arising and merging with the remnants  
 619 of the primary beta-gyre and forming a vortex pair with the main vortex and its  
 620 anticyclonic vorticity ring, with a clockwise-rotating axis. Contrary to the weak  
 621 vortex case, no clear tripolar structure is observed, and the cyclonic topographic  
 622 gyre is not aligned with the vorticity field of the topographic wave (see below).

623 We should emphasize that in simulations of [vanGeffen and Davies \(1999\)](#) the  
 624 vortex was always crossing the ridge, even a twice higher one, with respect to  
 625 the non-perturbed depth, compared to our set-up, and continued to move in  
 626 the north-west direction, although its trajectory was recurving over the bump.  
 627 Although a direct comparison is not straightforward, as the simulations in [vanGef-](#)  
 628 [fen and Davies \(1999\)](#) were done with the non-divergent model on the equatorial  
 629 beta-plane with  $f_0 \equiv 0$ , and the vorticity profile and intensity of the vortex were

FIGURE 15. Interaction of a weak TC -like vortex ( $ID : D1$ ) in the “dry” environment with a zonal Gaussian ridge with  $b_{max} = 0.2$ , as seen in the relative vorticity field (colours). Isolines of relative vorticity are zoomed out of the vortex core. Solid red lines: isolines of  $b$ .

FIGURE 16. Comparison of the tracks of a strong TC -like vortex ( $ID : D3, MC3$ ), left panel, and evolutions of the related peak relative vorticity (right panel) over the Gaussian ridge with  $b_{max} = 0.2$  in “dry” (white dots, solid line) and moist-convective (black dots, dashed lines) environments. Time span is from 0 to 465, and the interval between the dots is 15  $[L/U]$ .

630 different, this discrepancy emphasizes the role of divergence effects and related  
 631 vortex stretching, which are absent in the non-divergent model.

632 The evolution of moisture and condensation during the passage of a strong  
 633 TC over a zonal ridge is presented in figure 18. The condensation pattern  
 634 is similar to that of figure 13, but its intensity at the locations of primary  
 635 and secondary vortices is much higher. As follows from the figure, the first

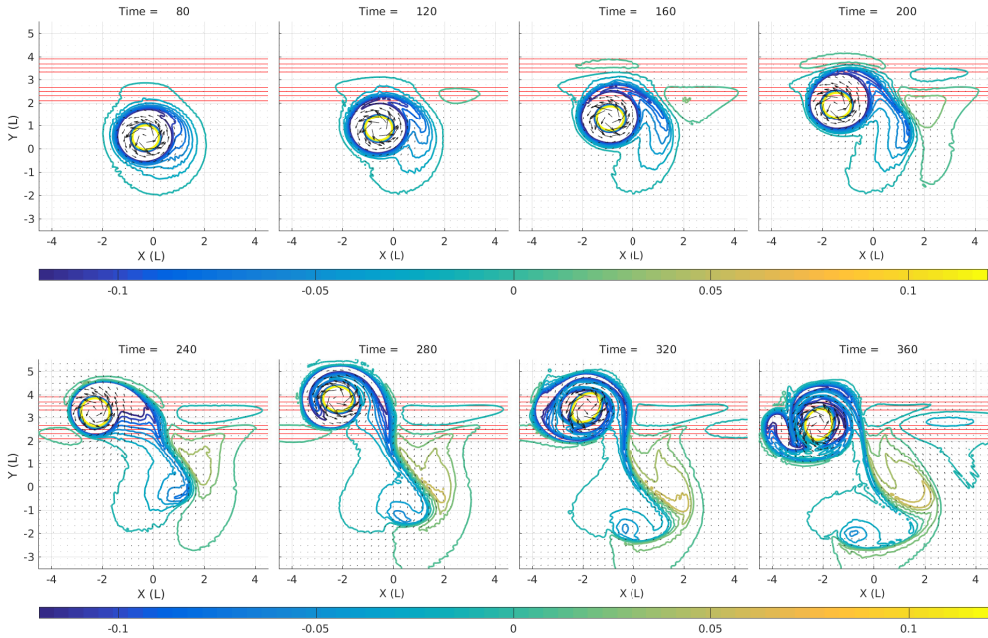

FIGURE 17. Evolution of relative vorticity of a strong TC-like vortex ( $ID : D3$ ) passing over a zonal Gaussian ridge with  $b_{\max} = 0.2$  (white dots in figure 16). Isolines of relative vorticity are zoomed over out of the core areas.

636 condensation pattern develops upwind and downslope, but then a second pattern  
 637 moving along the ridge appears. It is related to a topographic wave. The influence  
 638 of the moisture upon the trajectory can be inferred from figure 16. As follows  
 639 from the figure, the trajectories in the “dry” and moist - convective simulations  
 640 are qualitatively similar. As in the previous case of weak TC- like vortex, and  
 641 by the same reason, the trajectory in the moist-convective environment starts  
 642 the rightward shift earlier. The looping is explained similarly, although there is  
 643 a difference of curvatures of ‘dry’ and “moist-convective” trajectories. In view  
 644 of the “dry” evolution, with its stronger curvature, the variations of  $Q$ , and  
 645 related condensation (cf. figure 18) apparently contribute to the flattening of the  
 646 trajectory when the vortex exits the ridge. It should be not forgotten that effective  
 647 topography is higher in the moist-convective environment, as already explained.  
 648 The curves of the evolution of peak relative vorticity presented in the right panel  
 649 of figure 16 show a quasi-identical behaviour, apart from the fact that the peak  
 650 vorticity in the “moist-convective” case is higher during the periods when zones of  
 651 condensation are present, as it should be, as condensation enhances the cyclonic  
 652 vorticity. The consecutive minima of the peak vorticity starting at  $T = 235$   
 653 correspond to the repetitive passages by the TC of the topography maximum,  
 654 and, again, can be straightforwardly explained in terms of PV conservation. The  
 655 fact that high topography can trap intense cyclones arriving at incidence angles  
 656 close to  $90^\circ$  is quite remarkable. We will come back to this phenomenon in the  
 657 next section.

658 As follows already from the upper panel of figure 18, the passage of TC-

FIGURE 18. *Upper row*: Evolution of initially uniform moisture during a passage of a strong TC-like vortex (*ID* : *MC3*) over a zonal ridge with maximum  $b_{\max} = 0.2$  at  $y = 3$ . *Lower row*: Corresponding evolution of the condensation. Horizontal dotted lines indicate the position of the ridge.  $T = 235$  corresponds to the first minimum of the relative vorticity in figure 16.

659 I like vortices over the ridge produces pronounced convergence zones, as it is  
 660 only convergence or divergence of the velocity field which can redistribute the  
 661 initially uniform moisture. The corresponding evolution of the divergence field  
 662 is presented in the upper panel of figure 19, together with its counterpart for  
 663 the meridional bump (lower panel). As follows from the figure, a large-scale  
 664 topographic wave is generated during the encounter of the vortex with the  
 665 ridge, and starts propagating along the ridge. The divergence anomaly due to  
 666 this wave is at the origin of zonally propagating along the ridge patterns of  
 667 humidity anomaly and condensation. As is clear from the previous discussion,  
 668 the topographic wave also influences the dynamics of the vortex system over the  
 669 ridge in the case of the weak TC-like vortex.

#### 670 4.3. Interaction of TC-like vortices with an idealized Taiwan-like island

671 The Taiwan island, of a roughly elliptic form, with high mountains, is often  
 672 stricken by Western Pacific typhoons having a horizontal scale comparable to the  
 673 scale of the island. This is why observational and theoretical studies of interactions  
 674 of TC with such island are recurrent in the literature, e.g. (Chang et al. 1993;  
 675 Yeh and Elsberry 1993a,b; Kuo et al. 2001; Tang and Chan 2015; Wu et al.  
 676 2015; Tang and Chan 2016; Huang et al. 2016; Lin et al. 2016). The observed  
 677 TC tracks exhibit a variety of patterns with both northward and southward  
 678 deflections. They may be continuous or discontinuous, and can be accompanied  
 679 by formation of secondary lows (Chang et al. 1993; Yeh and Elsberry 1993b; Kuo

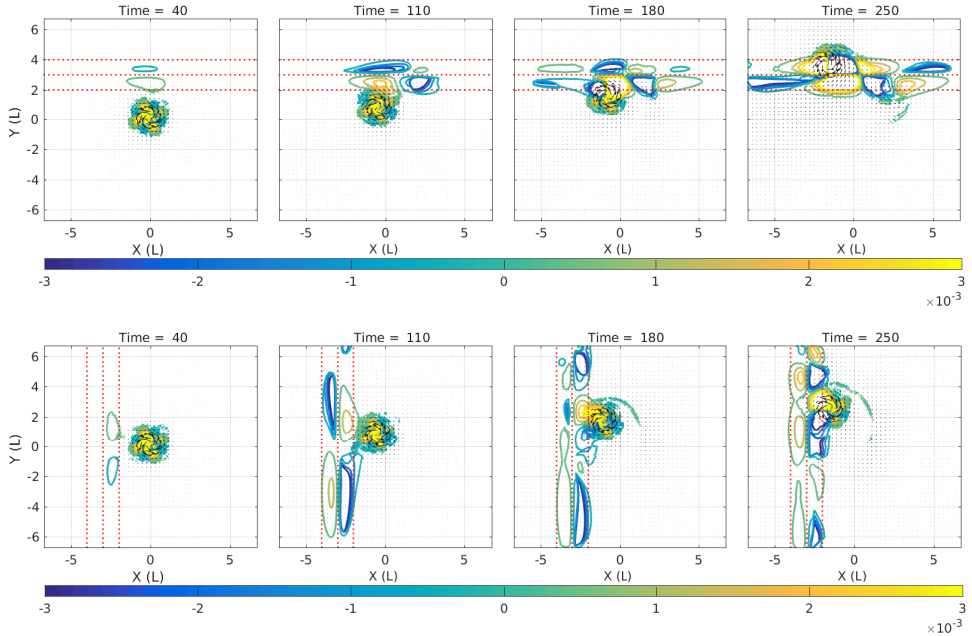

FIGURE 19. Isolines of divergence (colours) produced by a strong vortex (*ID : MC3*) passing over a zonal (*upper panel*) and a meridional (*lower panel*) ridges with  $b_{max} = 0.2$  in moist-convective environment. Small-amplitude signal corresponding to weak inertia-gravity waves produced during the encounter, and propagating radially out of the ridge, are filtered out.

680 et al. 2001). The process of deflection includes many environmental factors and is  
 681 very complicated, as stressed by Kuo et al. (2001). Many of the modelling studies  
 682 (Yeh and Elsberry 1993a; Wu et al. 2015; Huang et al. 2016; Lin et al. 2016)  
 683 use the simplistic  $f$ -plane approximation, with a meridionally oriented island  
 684 and an imposed easterly mean zonal wind which pushes the cyclone towards the  
 685 island. An accent was made on fully developed parameterizations of convection  
 686 and micro- physics, while the hydrodynamical set-up remained over-simplified in  
 687 recent works. The simulations of the TC trajectories near Taiwan on the beta-  
 688 plane with WRF model were performed in (Tang and Chan 2015, 2016). As is  
 689 clear from this short review, most of the modelling in this context was performed  
 690 with simplified models and the seminal study by Kuo et al. (2001) used the “dry”  
 691 shallow-water model.

692 In order to understand the role of hydrodynamic processes modified by crudely  
 693 parameterized convection, we undertook a similar study in the mcRSW on the  
 694 beta-plane. We recall that Kuo et al. (2001) demonstrated a possibility of full or  
 695 partial trapping of the cyclone by the island. We can hereby extend such study  
 696 by including together the beta-effect, the topography and the moist convection.

697 To represent an idealized Taiwan-like island we implemented a topography in  
 698 the form of a bump of elliptic shape with a Gaussian cross-section, with the  
 699 main axis oriented from south-west to north-east. The elevation of the bump was  
 700 chosen to be smooth, in order to prevent formation of hydraulic jumps and wave  
 701 breaking, with the maximal non-dimensional height  $b_{max} = 0.2$ . As is known from

FIGURE 20. *Left panel:* Comparison of trajectories of a weak TC- like vortex with  $Ro = 3.57, ID : MC1$  in the moist-convective environment in the presence (black circles), and in the absence (white circles) of the “Taiwan” island with  $b_{max} = 0.2$  (red isolines). Time interval between subsequent circles is  $15 [L/U]$ . *Right panel:* Same as in the left panel, but for a strong TC- like vortex ( $Ro = 10.37, ID : MC3$ ).

702 the above-cited literature, deflection during the approach and (partial) trapping  
703 by topography are the main features of the TC trajectories near the island. In  
704 order to check these effects in the mcRSW we initialized the TC-like vortices in the  
705 vicinity of the island, in a way that their trajectories, which were determined in  
706 the experiments of section 3.3, cross the location of the island. The initial moisture  
707 field was uniform, and close to saturation, as before. The numerical experiments  
708 were performed both with weak and strong TC, at different incidence angles  
709 with respect to the major axis of the island, and different incidence locations.  
710 Variations of the incidence angle were achieved by varying the orientation of  
711 the major axis of the elliptic bump, as we were using pre-calculated trajectories  
712 for initialization. The results on the track deflection of weak and strong TC-  
713 like vortices with RMW of the order of the transverse size of the island, and  
714 trajectories initially approximately perpendicular to this axis are presented in  
715 figure 20. As follows from the figure, both weak and strong TC- like vortices  
716 are partially trapped, and start moving along the clockwise path around the  
717 island, which is in agreement with some of the observed typhoon tracks across  
718 Taiwan, with the simulations of (Kuo et al. 2001), and also with the results of  
719 the section 4.2.2 above. The mechanism of recurving of trajectories due to the  
720 interactions of primary vortex, its beta-gyre, and topographic gyres was described  
721 in the previous section, and remains qualitatively the same. Its main ingredient  
722 is the primary cyclonic topographic gyre, which is clearly identified in figure 21,  
723 where we present the evolution of thickness during the landfall of strong and weak  
724 TC- like vortices. As is known from the observations, a secondary vortex can be  
725 formed at the lee side when a TC approaches the island, e.g. (Yeh and Elsberry  
726 1993a,b). As follows from figure 21 the secondary low is indeed generated at the  
727 northern side of the island during the passage of TC. After full intensification  
728 it detaches but its subsequent evolution depends on the incidence location and  
729 angle, see below. Such post-landfall phenomenon was documented, for example  
730 , in the observational study of the typhoon Mindulle (Lee et al. 2008). One  
731 of the practically important characteristics of the TC landfall on the island is

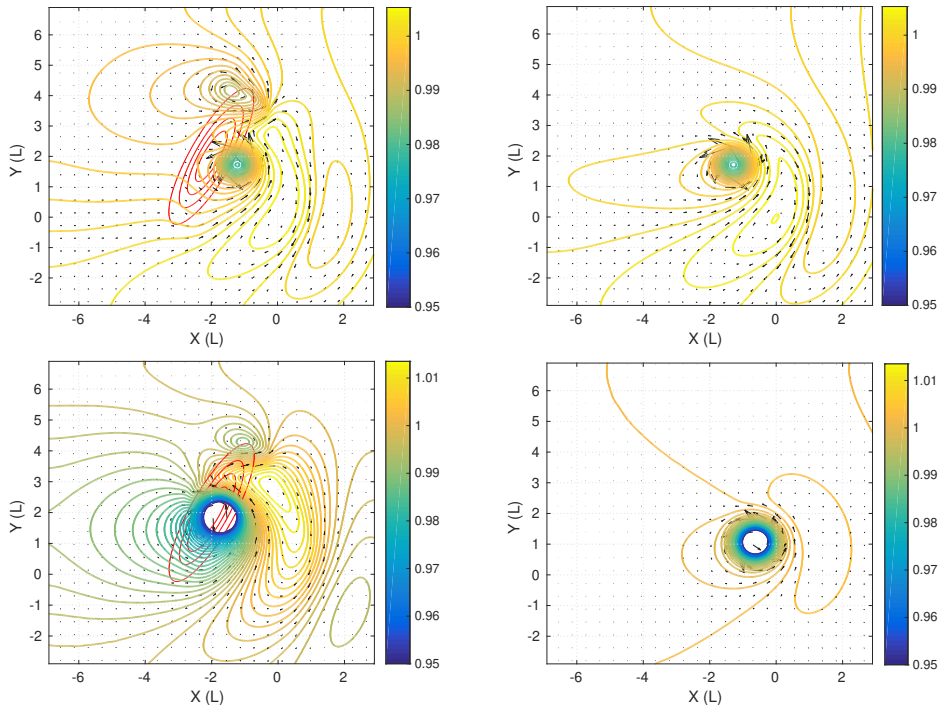

FIGURE 21. *Upper left (right) panel*: Selected isobars of a weak TC- like vortex ( $ID : MC1$ ) at  $T = 210$  in the presence (absence) of the “Taiwan” island. *Lower row*: Same as in the upper row, but for the strong TC- like vortex ( $ID : MC3$ ).

FIGURE 22. Spatial distribution of the accumulated condensation during the passage of strong TC - like vortex ( $ID : MC3$ , time span from 20 to 270[ $L/U$ ], (*left panel*)), and weak TC - like vortex ( $ID : MC1$ , time span from 20 to 500[ $L/U$ ], (*middle panel*)) over idealized Taiwan island. *Right panel*: spatially integrated condensation corresponding to the aforementioned cases: ( $ID : MC1$ , solid, and  $ID : MC3$ , dashed).

732 an amount of precipitation and its evolution in time. Accumulated amount, and  
 733 spatio-temporal evolution of condensation produced by the landfall of TC-like  
 734 vortices in the middle of the island, at incidence angle  $\approx 90^\circ$  are presented in  
 735 figure 22. It should be not forgotten that condensation and precipitation are  
 736 synonymous in the simplest version of the model we are using.

737 A panorama of the evolution of all essential fields during an encounter of  
 738 a TC - like vortex with the northern part of the idealized Taiwan island at  
 739 a smaller incidence angle is presented in figure 23. Typical convergence and  
 740 related condensation patterns are seen at the south-western and north-eastern

FIGURE 23. Spatio-temporal evolution of divergence, condensation, relative vorticity, and selected isobars of a weak TC - like vortex ( $ID : MC1$ ) passing over the northern part of idealized Taiwan island (red contours), respectively, from top to bottom.

741 parts of the island. Deformation of the beta-gyres because of the topographic  
 742 influence is clearly seen, as well as formation of a secondary low at the northern  
 743 tip of the island. The later stages of this landfall are presented in figure 24,  
 744 which continues figure 23, and exhibit s a rather complicated vortex system  
 745 comprising the primary vortex, the main anticyclonic beta-gyre, which intensifies  
 746 and becomes a rather intense localized anticyclonic vortex, and the topographic

747 gyre, which gives rise to a secondary cyclone. Overall, the vortex system evolution  
 748 scenario is similar to the one observed for the straight infinite ridge, cf. figure 15,  
 749 although the terminating topography introduces important new features. Thus,  
 750 the topographic gyre detaches from the island, and together with the primary  
 751 vortex and its anticyclonic beta-gyre forms a three-vortex system moving out of  
 752 the island. At the same time, a secondary cyclonic topographic gyre develops and  
 753 intensifies at the lee side of the island, as follows from figure 24. We should stress  
 754 that the peak vorticity of the main vortex is smaller than that of the detaching  
 755 topographic gyre during some period of time. A documented in the literature  
 756 process of a secondary low developing and replacing the original centre for TC  
 757 (Yeh and Elsberry 1993b; Lin et al. 1999; Wu 2001), as well as disruption of  
 758 trajectories of the observed TC during the landfall, e.g. Kuo et al. (2001), could  
 759 be explained by a process of this kind, as already in our simple model we see a  
 760 swap of the maximum vorticity between the primary and the secondary cyclones.  
 761 The corresponding trajectory of the primary vortex, the related evolution of its  
 762 peak vorticity, together with the peak anticyclonic vorticity, and comparison of  
 763 the peak vorticities of the primary and secondary cyclones are displayed in figure  
 764 25. As follows from the comparison of the left panel of this figure, and figure  
 765 20, trajectories of TC - like vortices are very sensitive to the landfall location  
 766 and incidence angle. The evolution of the anticyclonic vorticity in the middle  
 767 panel of figure 25 clearly shows the emergence of the secondary anticyclone, and  
 768 subsequent re-intensification of the primary cyclone, while the right panel displays  
 769 a swap of the maximum of vorticity between the primary and the secondary  
 770 cyclones. It is worth noticing that our results in the case described in figures 23 -  
 771 25 are similar to those obtained with the far more exhaustive WRF model, and  
 772 also with observational studies (Yeh et al. 2012; Tang and Chan 2016).

#### 773 4.4. *Resumé of the results on TC- like vortices interacting with topography*

774 The main feature of trajectories of TC- like vortices over the meridional and  
 775 zonal ridges is their recurving, which can lead to looping and trapping. This  
 776 behaviour is due to a rather complex vortex dynamics involving the primary  
 777 vortex, its beta-gyre, which is deformed and stretched during the passage over  
 778 the ridge, and of the primary cyclonic and secondary anticyclonic topographic  
 779 gyres, with an influence of the topographic wave generated during this process.  
 780 The condensation induced by the passage of TC-like vortices over the ridges  
 781 enhances the cyclonic vorticity and displays a specific pattern, which is correlated  
 782 with topographic waves generated during the interaction of the vortex with  
 783 topography, and propagating along the ridge.

784 The above-described features also manifest themselves when topography rep-  
 785 represents an elongated island. Although the recurving and partial trapping are also  
 786 observed, the terminating topography leads to appearance of “free” secondary  
 787 vortices, arising from the beta-gyres interacting with topography. These vortices  
 788 can have higher peak vorticity than the original vortex, which can explain seem-  
 789 ingly paradoxical disruptions of TC tracks over Taiwan reported in the literature.  
 790 The scenarios of the landfall strongly depend on the angle of incidence and its  
 791 location at the island. We should add that many of the detected in this part of the

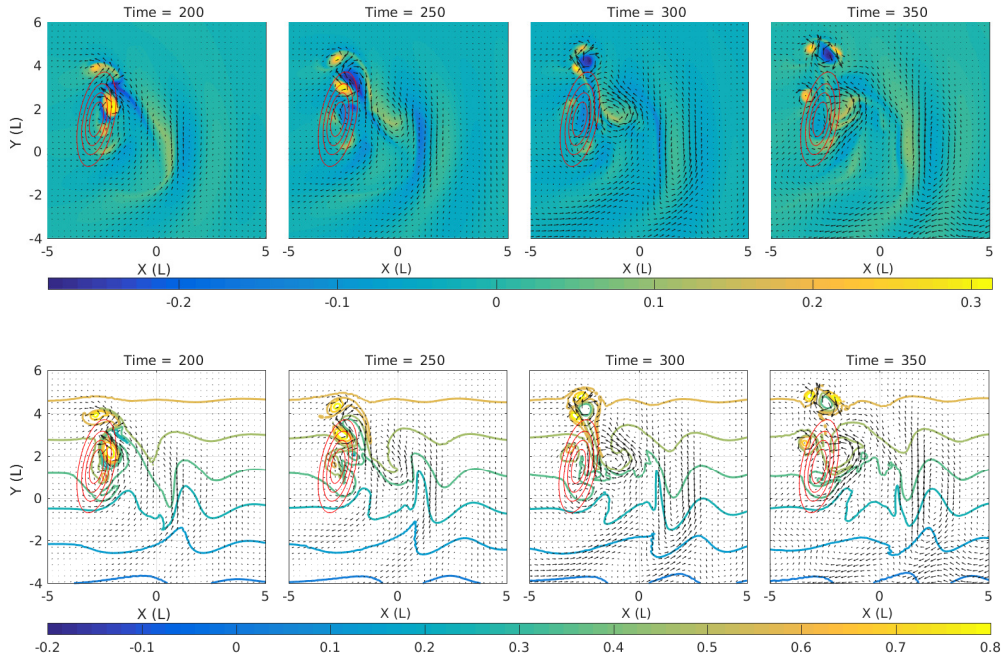

FIGURE 24. Late stages of the evolution of relative vorticity (*upper row*) and PV (*lower row*) of the landfall of weak TC - like vortex (*ID : MC1*) continuing figure 23

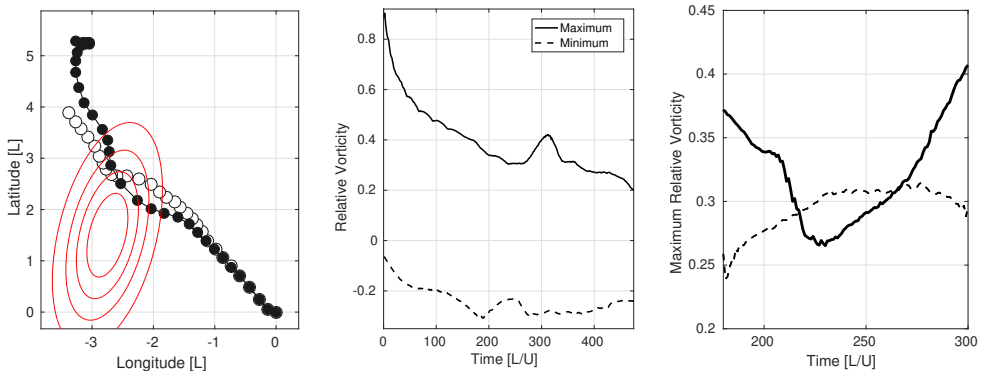

FIGURE 25. *Left panel*: trajectory of a TC - like vortex hitting the northern part of the “Taiwan” island with  $b_{max} = 0.2$  (red contours) in the moist-convective environment (black circles) compared to that without topography. Time interval between the circles is 15  $[L/U]$ . *Middle panel*: Corresponding evolution of the anticyclonic (*dashed*) and cyclonic (*solid*) peak relative vorticities. *Right panel*: Swap of the maximum of vorticity between the primary vortex (*solid*), and the secondary (*dashed*) terrain-induced cyclone.

792 study features are also observed in “dry” simulations with the same topography,  
 793 which we do not present. Yet, the moist convection boosts secondary cyclones,  
 794 and makes their influence more pronounced.

## 5. Summary and discussion

We have, thus, shown that the mcRSW model produces evolution and trajectories of TC- like vortices, which are qualitatively and quantitatively close, within the limits of the model, to the observations of TC and the results of studies with much more sophisticated models. The main advantage of the model is simple and computationally friendly incorporation of crudely parametrized moist convection, and of arbitrary topography. The simplicity of the model, and the robustness of modern finite-volume numerical schemes, allows for long-time high-resolution simulations, and hence for efficient tracking of the intense cyclonic vortices in different environments. We thus, have shown that TC-1 like vortices in the Northern hemisphere experience the north-western beta-drift, which is significantly influenced by the moist-convective phenomena in the case of strong vortices. Our main discovery in this direction is that, in the absence of the mean wind, the strong cyclones are travelling much farther North than their weak counterparts, and experience, after some time, a north-eastern turn, with a northward displacement being more pronounced in the presence of the moist convection. Such turns are reported in the observations of TC, but are usually attributed to the influence of the mean wind. We have also shown that the intrinsic instabilities of the intense hurricane-type vortices, which were previously identified in the  $f$ - plane approximation, are triggered by the beta- effect, and evolve on the beta-plane as well, although with asymmetric distortions due to the presence of the beta-gyres. They lead to formation of secondary eyewall meso-vortices which, in turn, evolve, merge, and lead to intensification of the vorticity in the vortex core. Meso-vortices are recurrently reported in the observations of TC. The moist convection enhances the effect of intensification, while the instability mode with azimuthal wavenumber one, which appears due to the beta-effect, does not qualitatively change the evolution of the main instability and the dynamics of meso-vortices. We have demonstrated that the evolution of TC- like vortices leads to enhanced inertia gravity wave activity in the moist-convective environment, the peaks in the wave activity being correlated with different stages of the evolution of the meso-vortices. Concerning the condensation, we found a distinct asymmetry in the aggregate condensation between north-western and south-eastern sectors with respect to the vortex centre, again, in accordance with observations of TC.

Using the advantage of easy and numerically friendly incorporation of topography in the shallow-water model, we analysed the passage of TC- like vortices over a ridge-like and mountain island like topographies and demonstrated trapping of the cyclones by topography, accompanied by generation of topographic waves, which influence the condensation/precipitation patterns. The character of the trapping (full or partial) depends both on the intensity of the cyclones and on the characteristics of topography. Our simulations reveal rich patterns of vortex dynamics, involving the primary vortex, the main anticyclonic lobe of its beta-gyre, and the topographic cyclonic gyres, which determine the trajectory and the evolution of the intense vortices. In the context of deflection of the TC tracks over the mountain Taiwan-like island, we observed several scenarios, from deflection to trapping, depending on the strength of the cyclone, incidence angle and landfall location. We found, again, complex scenarios of vortex dynamics

841 of the primary cyclone, a secondary cyclone arising from the topographic gyre,  
842 and an anticyclone produced by the beta-gyre, with swaps of the maximum of  
843 vorticity between the primary and the secondary cyclones. Such scenarios can  
844 shed light on the observed disruptions of the TC trajectories.

845 On the basis of the present study we can conclude that the mcRSW model  
846 is able to capture some of essential dynamical features of TC and allows  
847 for semi-quantitative predictions of trajectories and intensities of TC at low  
848 computational cost. In particular, our investigation of interactions of TC- like  
849 vortices with topography reveals complex dynamical patterns and high sensitivity  
850 of the observed scenarios to various parameters, although the number of these  
851 latter is massively reduced as compared to “big” models. This shows, on the  
852 one hand, an intrinsic difficulty and complexity of the landfall forecasts but, on  
853 the other hand, a utility of simple models, because while a thorough analysis  
854 of landfall scenarios with mcRSW is affordable, this is hardly the case of “big”  
855 models.

856 It is important to emphasize that the model can be further improved by  
857 including precipitable water in a liquid phase, together with vaporization, and its  
858 baroclinic two-layer version is also available [Rostami and Zeitlin \(2018\)](#). Radiative  
859 cooling and surface drag can be straightforwardly incorporated, as well, ensuring  
860 more realism. However, already the present results, obtained in the most simple  
861 version, clearly demonstrate the potential of the model.

862 Let us finally stress that, independently of tentative utility for TC- related  
863 applications of the results in the moist-convective environment, their “dry”  
864 counterparts presented above contribute to better understanding of the dynamics  
865 of intense vortices, by providing new, and sometimes unexpected, information on  
866 their behaviour on the beta-plane and their interactions with topography, like, for  
867 example north-eastern deflection of trajectories, and swaps of vorticity maxima  
868 between primary and secondary vortices over the island.

869 **Acknowledgements** This work was supported by the French National Pro-  
870 gram LEFE-MANU, and the German Research Foundation within the framework  
871 of the CRC 806 (project ID 57444011).
