21 **Abstract:** The long-term safety of shallow disposal facility for short-lived low and intermediate
22 level nuclear waste (LLW/ILW) relies on the performance of engineered barriers (caps and liners).
23 Soil-atmosphere interaction may affect the capping material at shallow depths, due to changes of
24 its coupled hydro-thermal-mechanical behavior under the effect of atmospheric conditions. This
25 study aims to investigate the soil-atmosphere interaction at different time scales in the overburden
26 of an LLW/ILW disposal facility, located in middle France. Actual meteorological data from
27 Valencia El Saler station in Spain, including solar radiation, air temperature, latent heat, rainfall,
28 and actual evaporation, at four different time scales (30 min, daily, weekly and monthly), were
29 applied as the future climate conditions of the studied area based on climate analogues. A numerical
30 approach combining a coupled hydro-thermal model and a soil-atmosphere interaction model was
31 employed. Results show that the employment of meteorological data at a short time scale (30 min)
32 can increase the simulation accuracy by capturing the extreme climate events and accelerating the
33 soil-atmosphere interactions. Furthermore, the effect of future climate conditions in the long-term
34 (7 years) on soil hydro-thermal behavior was examined. This enables a further detailed inspection
35 of the climate's role in the LLW/ILW storage system.

37 information; Different time scales; Long-term estimation

38

39 **1. Introduction**

40 Nuclear waste is currently being disposed at a number of facilities all over the world [1–3].
41 Considering the decay of radioactivity, a near-surface type of disposal facility is usually proposed
42 for the short-lived low and intermediate level nuclear waste (LLW and ILW) [4]. By contrast, the
43 solution for the disposal of high-level and other long-lived nuclear waste (HLW) is a deep
44 geological repository [2,5]. In the case of LLW/ILW repository, soil-atmosphere interaction may
45 affect its capping material at shallow depths by the physical process of heat and mass transfer over
46 time. For instance, cracks may be produced as a consequence of long dry and hot periods,
47 significantly modifying the thermo-hydro-mechanical properties of the capping material;
48 contaminant transport in the host geologic formation may be accelerated due to changes in soil
49 temperature, water content and suction from weathering, etc. [6,7]. Hence, the effect of climate
50 change must be considered in the assessment of the long-term performance of LLW/ILW disposal.

51 Soil–atmosphere interaction drives water, energy and biogeochemical cycles, causing variations
52 of soil moisture, temperature, and suction, etc. [8–10]. Over recent years, increasing awareness
53 about the importance of soil-atmosphere interaction has led researchers to investigate the potential
54 effect of climate change on the performance of waste covers and nuclear waste handling [11–16].
55 Fischer [13,14] undertook studies to determine the rates and directions of water movement through
56 unsaturated sediments for the assessment of the contaminant movement near an arid LLW disposal
57 facility. Phillips et al. [15] studied the mineral behavior and transformations brought on by climate
58 change may affect the long-term performance of the cap and even the LLW disposal facility. Nasir
59 et al. [16] investigated that both permeability and porosity of the near field sedimentary host rocks
60 for the LLW/ILW disposal increase as a result of climate change. In summary, the evaluation of
61 waste covers in terms of waste isolation and contaminant transport requires details of subsurface

62 flows which are significantly affected by climatic fluctuations. Specifically, the major threat to the
63 integrity of nuclear waste isolation in the near-surface type of disposal facility is the water
64 infiltration due to the potential movement of dissolved and mobilized radioactive constituents.
65 Therefore, considering the long life of radioactive waste, it is of paramount importance to well
66 determine the hydro-geologic characteristics of an LLW/ILW disposal facility in order to limit
67 water flow in the vicinity of the disposal facility [13,14].

68 The soil hydraulic condition in the overburden of LLW/ILW disposal facilities is governed by
69 precipitation and evapotranspiration which are associated with the changing climate conditions.
70 Generally, long-term climatic cycles present a low frequency and small amplitude, having less
71 impact on the capping material. However, the low-frequency extreme weather events, such as a
72 long-term drought, may result in significant damage to cap materials [15,17]. The fundamentals of
73 the safety assessment of waste disposal facilities of LLW/ILW/HLW in Belgium were discussed
74 by van Geet et al. [12], emphasizing the importance of considering climate evolution. However, to
75 the authors' knowledge, no study has been undertaken to investigate the soil-atmosphere
76 interaction in the LLW/ILW overburdens under the effect of future climate conditions.

77 This study aims at better understanding the soil-atmosphere interaction in the overburden of the
78 LLW/ILW disposal facility, through identifying the soil coupled hydro-thermal responses to the
79 future climate changes. A numerical approach combining a coupled hydro-thermal model and a
80 soil-atmosphere interaction model was employed and implemented through the Finite Element
81 Method using FreeFem++ code [18]. Considering climate analogues, actual meteorological data
82 collected from Valencia El Saler station was employed as the future climate condition of the studied
83 site located in middle France. Firstly, the meteorological data in the year 2000 collected at the time
84 intervals of 30 min, daily, weekly, and monthly, were used to investigate the effect of the time scale

85 of climate conditions on the hydro-thermal behavior of the overburden soil. Moreover, the
86 influence depths in terms of soil water content and temperature at different time scales were
87 examined, respectively. Secondly, the meteorological data at the time scale of 30 min for a longer
88 period from 2000 to 2006 (7 years) was employed to investigate the long-term soil-atmosphere
89 interaction and the influence depths in terms of soil temperature and water content.

90

91 **2. Investigated site**

92 The studied site which was devoted to the storage of short-lived LLW/ILW was located at
93 Soulaines (Aube), France. Figure 1a plots its stratigraphic profile, including three layers: a layer of
94 nature backfill soil, a 5 m superficial layer and a natural Teguline clay layer of 50 to 70 m thickness.
95 Specifically, the excavated zone is at a depth of -20~-30 m and the storage space for LLW/ILW is
96 at a depth of -25~-35 m.

97 For further study, the studied region is simplified as three layers with homogeneous soil for each
98 (Figure 1b). The primary soil information of each layer is detailed in Table 1. The soil temperature
99 at the bottom zone of the studied region was measured as 14°C [19]. The local water table was
100 close to the bottom boundary of the natural Teguline clay layer. The soil thermal conductivity,
101 water retention curve and hydraulic conductivity curve of each layer are detailed as follows.

102 *2.1 Layer 1 (L1)*

103 In terms of silt clay as the backfill material of L1, its parameters used for the assumed simulations
104 were estimated from results obtained on a soil comparable to that at the site. The variation of soil
105 thermal conductivity versus its volumetric water content is expressed in a linear relationship by
106 equation (1) [20,21] (Table 2) and plotted in Figure 2a. The soil water retention curve (Figure 2b)

107 can be described by van Genuchten model [22–24]. The relevant parameters in equation (2) are
108 listed in Table 2. Based on the soil water retention curve, its hydraulic conductivity curve is
109 determined by equation (3) and drawn in Figure 2c. The saturated soil hydraulic conductivity is
110 estimated as 1.0×10^{-8} m/s [25].

111 2.2 Layer 2 (L2)

112 KD2 instrument [26] was used herein to measure the thermal conductivity of the compacted
113 Teguline clay. A linear relationship between soil thermal conductivity and volumetric water
114 content is considered to fit the measured results [27,28]. The proposed relationship is expressed by
115 equation (4) and presented in Figure 2a. Similar to the case of L1, van Genuchten model [24] is
116 used to describe the variations of soil water retention and hydraulic conductivity of L2. Based on
117 the measured data obtained by Cuisinier and Masrouri [29], the fitting curve is drawn in Figure 2b,
118 providing the values of van Genuchten model parameters in Table 2. The hydraulic conductivity
119 curve is determined with the measured saturated hydraulic conductivity 1.4×10^{-9} m/s [29] (equation
120 (3) and Figure 2c).

121 2.3 Layer 3 (L3)

122 As far as the natural Teguline clay is concerned in L3, the thermal conductivity was measured by
123 Zhang et al. [30], presenting slight variations versus soil dry density and water content. Therefore,
124 its soil thermal conductivity is considered as a constant value of 2 W/(m.K) for the purpose of
125 simplification. Based on the measured data obtained by Zeng et al. [31], the variations of soil water
126 retention and hydraulic conductivity of L3 are described by equations (2) and (3). The fitting curves
127 are plotted in Figures 2b and 2c, respectively. The measured saturated hydraulic conductivity is
128 3.0×10^{-12} m/s.

129 *2.4 Meteorological information*

130 Hallegatte et al. [32] presented a type of climate relocation based on the concept of spatial climate
131 analogues, which specifies that a location that presently enjoys a climate close to the one another
132 city will experience in the future (the end of the twenty-first century). Based on the acceptable
133 analogues of climate relocation, the studied site in the central part of northern France may
134 experience an eastern Spain type of climate in the future [33,34]. Thereby, the actual
135 meteorological data collected from Valencia El Saler station was employed to represent the future
136 climate conditions that the studied site located in middle France may experience. It is worth noting
137 that in the current knowledge of climate change, the predicted future local climate conditions are
138 always attached with uncertainties due to the limitations of climate models, internal climate system
139 processes and socio-economical, demographic or technological evolutions. The measured solar
140 radiation, air temperature, latent heat, rainfall and the estimated actual evaporation rate from
141 01/01/2000 to 31/12/2000 are plotted in Figure 3 at different time scales (30 min, daily, weekly
142 and monthly respectively). They were used to study the effect of climate conditions at different
143 time scales on the interaction between soil and atmosphere. Figures 3a, 3b, and 3c demonstrate the
144 diurnal and seasonal variations of solar radiation, air temperature, and latent heat, with higher
145 values in the summer period and lower values during the wintertime. However, it is observed that
146 rainfall data does not vary seasonally (Figure 3d). Similar to the results of latent heat, evaporation
147 data presents the highest value in summer (Figure 3e). In addition, the comparison of each climate
148 factor at different time scales suggests that the smaller fluctuations are obtained at a longer time
149 scale. Especially, the extreme climate conditions, such as the highest temperature and the most
150 torrential rainfall events, can be identified at the time scale of 30 min.

151 Furthermore, meteorological information at the time scale of 30 min in the period from
152 01/01/2000 to 31/12/2006 (7 years), was employed to study the long-term soil hydro-thermal
153 behavior (Figure 4) in the future. The annual variations of solar radiation, air temperature, latent
154 heat, rainfall, and the estimated evaporation are plotted in Figures 4a~e, respectively, displaying
155 an apparent seasonality. The peak values of solar radiation (Figure 4a) and air temperature (Figure
156 4b) are observed in summertime and wintertime of each year. Specifically, the magnified image of
157 solar radiation above 800 W/m² displays an increasing trend, reflecting the warming climate
158 condition as time continues. The effect of climate change on the variations of latent heat and
159 evaporation is identified by higher values of latent heat and evaporation in the wintertime of years
160 2003, 2004, 2005 and 2006 than those of the years 2000, 2001 and 2002. Besides, more frequent
161 rainfall events (Figure 4d) are recorded in the years 2003, 2004, 2005 and 2006.

162

163 **3. Numerical approach**

164 *3.1 Introduction of the numerical approach*

165 A numerical approach combining a coupled hydro-thermal model and a soil-atmosphere interaction
166 model developed by An et al. [10] was employed in this study. The coupled hydro-thermal model
167 was used to describe the coupled water and heat flow in unsaturated soil. The soil-atmosphere
168 interaction model was applied to describe the continuous water and heat transfer between soil and
169 atmosphere, which can be expressed by energy and mass balance, respectively. Details of the
170 numerical formulation and computational aspects have been presented by An et al. [10], and
171 therefore, they are not repeated herein.

172 *3.2 Model dimensions and boundary conditions*

173 Figure 5 displays the applied model dimensions: BC1 and BC 3 represent the bottom and top
174 boundaries, respectively; BC 2 and BC 4 are the lateral boundaries. The height and width of the
175 studied zone are 71 m and 10 m, respectively.

176 On the first day of the year 2000, the soil volumetric water content was measured as 5.8% and
177 the soil temperature was 11.67 °C at the ground surface. Meantime, the soil temperature was
178 measured to be 14 °C at the saturated bottom boundary (BC1). Thereby, the initial conditions about
179 soil temperature and water content/suction were defined in a linear relationship with depth. No
180 water and heat transfer were considered at the lateral boundaries. Based on the soil-atmosphere
181 interaction model, the soil heat flux and evaporation/infiltration were applied as the thermal and
182 hydraulic conditions at the top boundary, respectively. The details are explained as follows:

183 ***Energy balance***

184 In the case of heat transfer between soil and atmosphere, solar radiation is usually the only exterior
185 heat resource. Specifically, the net solar radiation equals the sum of latent heat, soil heat, and
186 sensible heat. The energy balance is described by:

$$R_n = G + L_E + H \quad (5)$$

187 where R_n (W/m^2) is the net solar radiation flux; G (W/m^2) is the soil heat flux; L_E (W/m^2) is the
188 latent heat flux; H (W/m^2) is the sensible heat flux. The net solar radiation at 30 min is estimated
189 by:

$$R_n = (1 - \alpha) R_{si} - \left[a_c \left(\frac{R_{si}}{R_{so}} \right) + b_c \right] (a_e + b_e e_d^{0.5}) \sigma (T_a^4) \quad (6)$$

190 where the solar radiation R_{si} (W/m^2) was measured as shown in Figure 3a; T_a ($^{\circ}C$) is the recorded
191 air temperature (Figure 3b); the definition and values of other parameters were detailed by An et
192 al. [10].

193 The measured values of latent heat at different time scales are introduced in Figure 3c.
194 Considering the convection of airflow in soil-atmosphere interaction, the sensible heat was
195 estimated following the same method presented by An et al. [10]. With the obtained values of net
196 solar radiation, latent heat and sensible heat fluxes at different time scales, the soil heat flux
197 boundary condition at the soil surface at the corresponding scale can be determined based on
198 equation (5).

199 ***Mass balance***

200 In terms of bare soil during rainfalls, water reaches the ground surface and infiltrates into the soil
201 continuously until the rainfall rate exceeds the soil infiltration capacity. In that case, the process of
202 runoff begins. However, it stops as soon as the rate of rainfall becomes lower than the actual rate
203 of infiltration. Meanwhile, evaporation occurs spontaneously due to the gradient in temperature
204 and relative humidity near the soil-atmosphere interface. The mass balance during soil-atmosphere
205 interaction is expressed as:

$$P = I_{nf} + R_{off} + E_a \quad (7)$$

206 where P (m/s), I_{nf} (m/s), R_{off} (m/s) and E_a (m/s) represent the rainfall, infiltration, runoff and actual
207 evaporation rates on soil surface, respectively. Field rainfall was monitored at different time scales
208 of 30 min, daily, weekly, and monthly (Figure 3d). Around 97% of the measured rainfall rates are
209 less than 5.5 mm/30min, which means that most of the runoff rates are in the range from 0.025 to

210 0.05 mm/30min [35]. Therefore, runoff is considered to be negligible in this study. Actual
211 evaporation rate (Figure 3e) was estimated based on the values of latent heat:

$$E_a = L_E / (\rho_w L_v) \quad (8)$$

212 where L_E (W/m^2) is the latent heat flux (Figure 3c); L_v (J/kg) is the latent heat of water vaporization;
213 ρ_w represents the water density (kg/m^3). With the available information about rainfall and actual
214 evaporation rates, the water flux boundary condition (I_{inf}) at the soil surface can be estimated at
215 different time scales.

216 Firstly, with the meteorological information collected every 30 minutes and soil parameters, the
217 numerical investigation was performed at a time step of 30 min for the year 2000. Afterwards, the
218 simulation scenarios at time scales of daily, weekly and monthly were implemented respectively,
219 at a time step of 1 day, for the year 2000 with the inputting data (rainfall, latent heat, air temperature,
220 and solar radiation, etc.) at the corresponding time scale. Finally, the simulation was carried out at
221 a time step of 30 min for 7 years (from 2000 to 2006) with the meteorological data at the time scale
222 of 30 min.

223

224 **4 Results and discussion**

225 *4.1 Soil hydro-thermal behavior at different time scales in one year (2000)*

226 4.1.1 Soil hydro-thermal behavior at the time scale of 30 min

227 Figures 6a and 6b depict the variations of soil volumetric water content and temperature at depths
228 of 0 m, -0.25 m, -0.5 m, -0.75 m, -1.0 m and -1.5 m in the year 2000. It appears that soil volumetric
229 water content increases significantly in response to rainfall events on 14/01/2000, 20/03/2000,
230 09/06/2000, and 22/10/2000, etc. It keeps a decreasing tendency as the result of evaporation during

231 the drying periods. As the depth increases, soil volumetric water content shows much smaller
232 fluctuations compared to that at near soil surface points (Figures 6a).

233 In terms of the soil temperature at the studied depths, they present a general increasing trend
234 from the winter to the summer, approaching the peak values on 18/08/2000. Afterwards, they start
235 to decline gradually until the end of the year 2000. The distinct seasonal variation of soil
236 temperature is observed with larger values in the summer and lower values in the winter (Figure
237 6b), showing a good agreement with the heat-related climate factors (solar radiation, air
238 temperature, etc.). Similar to the result of soil volumetric water content, the surface soil temperature
239 shows more significant variations compared to other depths.

240 To further explore the influence depth of the soil-atmosphere interaction, the calculated soil
241 volumetric water content and temperature profiles in the zone with depth 0~21 m are presented in
242 Figures 7a and 7b, respectively. The soil volumetric water content below -4.8 m keeps nearly stable,
243 indicating that the influence depth of climate conditions is limited to this value. Figure 7b shows
244 that the influence depth of climate conditions is limited to 12 m depth in terms of soil temperature.
245 Furthermore, a larger amplitude is identified in the profiles of soil temperature, compared to that
246 of soil volumetric water content, reflecting the significant contribution of the surface thermal
247 boundary conditions. It is therefore necessary to investigate the influence depths of temperature
248 and volumetric water content separately, as suggested by An et al. [10].

249

250 4.1.2 Soil hydro-thermal behavior at different time scales

251 The variations of soil volumetric water content at different time scales (30 min, daily, weekly,
252 and monthly) are plotted for depths 0 m (Figure 8a), -0.25 m (Figure 8b), -0.75 m (Figure 8c), and
253 -1.5 m (Figure 8d), respectively. At each depth, a similar variation tendency is observed among the

254 results of soil volumetric water content at different time scales. Generally, the results at the time
255 scale of 30 min depict the maximum and minimum values, except the unexpected daily results on
256 21/03/2000. In the daily results on the soil surface (Figure 8a), soil water content increases sharply
257 to 35% on 21/03/2000 and then exhibits a general decreasing trend with a few jumps due to rainfall
258 events until 11/06/2000. The daily results show a consistent variation mode as the 30 min results
259 but with a higher value over the dry periods, suggesting the continuous effect of the unexpected
260 daily rainfall data on 21/03/2000. In the same rainfall event, a more significant increase in water
261 content is observed in the 30 min results compared to other results. This suggests that a time scale
262 as short as 30 min is capable of increasing the accuracy of simulation results by accelerating the
263 iteration rate of soil-atmosphere interaction. Furthermore, the daily fluctuations of soil water
264 content are more evident at the time scale of 30 min than others, especially for the period with
265 intense rainfall (23/10/2000 to 31/12/2000).

266 Figure 9 plots the evolutions of the soil temperature at different depths at different time scales
267 (30 min, daily, weekly, and monthly). It appears that at the soil surface, the fluctuations are more
268 significant at the time scale of 30 min than others (Figure 9a). As the studied point goes deeper,
269 the difference between the soil temperatures at different time scales is becoming smaller.

270 The simulated soil volumetric water content and temperature profiles at time scales of daily,
271 weekly and monthly are plotted in Figures 10a, 10b, and 10c, respectively. The influence depths
272 of climate conditions on soil volumetric water content are about 5.2 m, 11.6 m, and 11.6 m at the
273 time scales of daily, weekly, and monthly, respectively. They are larger than that of 30 min (4.8
274 m). This is attributed to the effective mass interaction between soil and atmosphere at the time scale
275 of 30 min. On one hand, rainfall events occur during some specific periods rather than continue at
276 a constant rate for daily/weekly/monthly. Hence, soil water content varies more quickly due to the

277 rainfall at the time scale of 30 min than those of other time scales. On the other hand, due to the
278 monthly average evaporation rate at the soil surface, water content at the time scale of monthly
279 decreases for a longer period compared to others (Figure 8d). Thereby, when the
280 evaporation/rainfall at the time scale of 30 min is applied as the hydraulic boundary condition, they
281 lead to a shallower influenced zone compared to the results of other time scales.

282 On the other hand, similar to that of 30 min results, the influence depths of climate conditions
283 on soil temperature is limited to around 12.0~12.8 m at time scales of daily, weekly, and monthly.
284 The effect of time scale on the influence depth of climate conditions in case of soil temperature is
285 not significant as the results of soil water content. It may be attributed to the participation of soil
286 surface temperature in the estimation of sensible heat and hence the value of heat flux boundary
287 condition, which may lead to the same amount of energy transfer between soil and atmosphere at
288 different time scales. Additional work is required to further clarify this point. In the region below
289 the influenced zone, both soil volumetric water content and temperature remain stable as their real
290 initial conditions during the studied period. It is thereby suggested to measure the real initial soil
291 conditions in the area of interest for the evaluation of LLW/ILW storage system's performance.

292

293 *4.2. Soil long-term hydro-thermal behavior for 7 years (2000-2006)*

294 4.2.1 Variations of soil volumetric water content and temperature

295 Figure 11a plots the changes in soil volumetric water content at different depths (0 m, -0.25 m, -
296 0.75 m, and -1.5 m) from 01/01/2000 to 31/12/2006. It is observed that soil volumetric water
297 content increases because of rainfall and keeps a decreasing tendency due to evaporation in the
298 drying periods. Moreover, soil volumetric water content at the surface point shows much larger
299 fluctuations compared to that of other depths.

300 The evolutions of the soil temperature at different depths during the studied period are illustrated
301 in Figure 11b. Soil temperatures at these studied points present apparent seasonal variations with
302 larger values during the summer period and smaller values in the wintertime. A larger variation
303 amplitude of soil temperature is also identified at the soil surface than other depths. Moreover, over
304 time, the peak temperature in the summer goes up gradually, evidencing the effect of climate
305 change on soil temperature in the long term.

306

307 4.2.2 Influence depths

308 Soil volumetric water content profiles at different times at depths of 0~21 m during the years 2001,
309 2002, 2003, 2004, 2005, and 2006 are plotted in Figure 12, respectively. The influence depths of
310 climate conditions on soil volumetric water content vary slightly for different years: 4.0 m for the
311 year 2001 (Figure 12a), 4.8 m for the year 2002 (Figure 12b), 6.0 m for the year 2003 (Figure 12c),
312 3.2 m for year 2004 (Figure 12d), 8.0 m for year 2005 (Figure 12e) and 10 m for year 2006 (Figure
313 12f). Among the studied period, the influence depth in terms of soil water content presents the
314 largest and smallest values in the years 2006 and 2004, respectively. However, more frequent
315 rainfall events (Figure 4d) are recorded in the years 2003, 2004, 2005 and 2006. It infers that the
316 relationship between the influence depth and the changing climate conditions is not significant as
317 expected. This may be attributed to that the value of net water flux conditions is governed by both
318 rainfall and evaporation on the soil surface.

319 On the other hand, the soil temperature profiles in different years (2000 to 2006) at depths of 0~
320 21 m are shown in Figure 13, presenting the influence depths of climate conditions: 18.4 m in the
321 year 2001 (Figure 13a), smaller than 20 m in other years (Figures 13b~f). The influence depth of
322 climate conditions on temperature increases as time continues. It is inferred to be related to the

323 warming climate conditions produced by the increasing solar radiation from the year 2000 to the
324 year 2006 in Figure 7a.

325 As shown in Figures 12h and 13h, in the studied period of seven years (2000 to 2006), the
326 influence depths of climate conditions are estimated to be larger than 20 m for both soil water
327 content and temperature. It indicates that the overburden and the current storage space for
328 LLW/ILW are potentially situated in the weather influenced zone in the future. Therefore, further
329 investigation about the effect of soil water content and temperature on the performance of
330 LLW/ILW storage system is required to minimize the negative weather influence on LLW/ILW
331 storage and to provide a practical suggestion for future site selections. Based on the results of each
332 year and seven years, it is inferred that the influence depths of climate conditions vary significantly
333 in different studied periods. The differences are governed by the climate conditions of the studied
334 periods. During the longer studied period (7 years), the influence of climate conditions on the
335 variations of soil volumetric water content and temperature is accumulated, leading to a deeper
336 influenced zone compared to that of each year. It may be attributed to the effect of wetting-drying
337 cycles during the longer period on the changes of soil microstructure, allowing heat and water
338 transport to a deeper zone.

339

340 **5. Conclusions**

341 In this study, the effect of climate conditions on soil water content and temperature in the
342 overburden of LLW/ILW disposal facility were numerically investigated at different time scales
343 (30 min, daily, weekly and monthly) and in the long term (7 years). Actual meteorological
344 information data from Valencia El Saler station in Spain were used as the future climate conditions

345 of the studied site in middle France based on climate analogues. The obtained results allow the
346 following conclusions to be drawn:

347 (1) The variations of soil volumetric water content and temperature in the near-surface zone
348 are mainly affected by the hydraulic (evaporation/infiltration) and thermal (soil heat flux)
349 boundary conditions at the soil-atmosphere interface. At soil surface, distinct daily and
350 seasonal variations of soil temperature can be observed, with higher values during the
351 summer period and lower values in the wintertime. In the deeper zone, both soil volumetric
352 water content and temperature show much smaller fluctuations compared to those of near
353 soil surface zone.

354 (2) The calculated results in terms of soil volumetric water content and temperature present a
355 similar variation tendency at the same depth for the four different time scales. However, in
356 general, the results at the time scale of 30 min depict the maximum and minimum values
357 because of the extreme climate events recorded at this time interval. The daily fluctuations
358 of soil water content and temperature are more evident at the time scale of 30 min than
359 those of other time scales, especially at soil surface point. As a result, the employment of
360 meteorological information at a short time scale (30 min) can increase the accuracy of
361 simulation results by capturing the extreme climate events and accelerating the iteration
362 rate of soil-atmosphere interaction. Thereby, it is suggested to apply the meteorological
363 information at a short time scale (30 min) to estimate the soil hydro-thermal behavior in the
364 geotechnical and environmental contexts.

365 (3) In terms of influence depth for soil water content in the year 2000, it is limited to 4.8 m, 5.2
366 m, 11.6 m, and 11.6 at the time scale of 30 min, daily, weekly, and monthly, respectively.
367 The mass transfer between soil and atmosphere at the time scale of 30 min is more effective

368 than others. However, the influence depth in terms of soil temperature is limited to
369 12.0~12.8 m, indicating the insignificant effect of time scale. It may result from the same
370 amount of energy transfer between soil and atmosphere at different time scales. Additional
371 work is required to further clarify this point.

372 (4) The change of soil temperature in the long term (7 years) indicates that the peak
373 temperatures of the summer periods show an increasing trend from 01/01/2000 to
374 31/12/2006, reflecting the effect of the warming climate on soil temperature. Moreover, the
375 influence of climate conditions on soil hydro-thermal behavior is accumulated over time,
376 leading to a deeper influenced zone (> 20 m) in a longer studied period. It indicates that the
377 overburden and the current storage space for LLW/ILW are potentially situated in the
378 weather influenced zone in the future.

379 (5) This study infers that a further investigation about the effect of soil water content and
380 temperature variations on the performance of LLW/ILW storage system is required. It also
381 enables a further detailed inspection of climate's role in the LLW/ILW storage system to
382 minimize the negative influence of climate change on LLW/ILW storage and to provide a
383 practical suggestion for site selections.

384
